Water samples from the unused Park well (F1) have differed in chemical character and contained more dissolved minerals. They have been sodium chloride in character with electrical conductances ranging between 2,370 and 4,130 micromhos/cm (equivalent to mineral concentrations of 1,540 and 2,680 mg/l). The source of the high salinity appears to be directly related to salts contained within the Bouse Formation. However, it could be partially related to decaying vegetation. Discharge from the well is reported to have had a hydrogen sulfide odor and an elevated temperature. As shown by the SO_4/Cl ratios in Table 1, the chemical character of the well discharge is related to the duration of

E-85417-B

pumping. Initial discharge was chloride in character, but after a few hours of pumping, the sulfate concentration almost doubled. It appears that long duration pumping had the effect of inducing a westward migration of sulfate water that must be present between Well F1 and the RO plant.

Initially, Well F1 obtained water from two separate aquifers, as shown on Figure 2. The aquifers are separated by a silt and clay aquitard 40 to 70 feet in thickness that probably occurs beneath most of the Park. Both aquifers yield a chloride water, but after the deeper confined aquifer was sealed during December 1961, ground water could only be obtained from the upper unconfined aquifer which contains high concentrations of sulfate.

As shown by Figure 2 and Table 1, Exploratory Boring No. 1 encountered a sodium sulfate water in the upper aquifer and a sodium chloride water in the deeper aquifer. Water in the upper aquifer has a lower concentration of dissolved minerals than water yielded by the gravel collector, but would still require some demineralization to be suitable for drinking water. Ground water in the deeper aquifer is more mineralized and would similarly require demineralization prior to use for drinking water.

Exploratory Boring No. 3 also penetrated the two aquifers penetrated by Well F1 and Boring No. 1, but the upper aquifer was unsaturated. Ground water in the deeper aquifer above a depth of 200 feet is considerably different in chemical character and mineralization

than the water obtained from Well F1 and Boring No. 1. It is a sodium bicarbonate water with a low total dissolved mineral concentration of 525 micromhos/cm. It is generally suitable for drinking water with several restrictions. Below a depth of 200 feet, ground water is sodium chloride in character which is similar to the water encountered in the deeper aquifer at Well F1 and Boring No. 1. The water sample collected at 250 feet had an electrical conductance of 1,190 micromhos/cm and would be only marginally suitable for drinking water.

The water sample collected from Boring No. 3 at a depth of 160 feet indicates that the ground water in the vicinity of the boring site is suitable for drinking water with several exceptions. As shown in Table 1, the sample had a fluoride concentration of 1.8 mg/l, which is slightly above the recommended maximum contaminant level (MCL) of 1.4 mg/l for the average of maximum daily air temperature of 86.4 degrees F which has been recorded at Needles. However, the EPA is proposing a recommended MCL of 4.0 mg/l. If the MCL is adopted in California, the fluoride concentration in ground water in the vicinity of Boring No. 3 would be acceptable. An MCL is the highest concentration of a particular contaminant that is allowed in drinking water. The sample also contained excessively high concentrations of iron (6.8 mg/l) and manganese (0.52 mg/l). Concentrations of other elements found in the sample from 160 feet for which MCL's have been established are shown in Table 2. The laboratory report is presented in Appendix B.

Table 2
CONCENTRATIONS OF MINOR ELEMENTS
(concentrations in mg/l)

Element	Concentration	MCL
Copper	< 0.007	1.0
Iron	6.8	0.3
Manganese	0.52	0.05
Zinc	0.019	5.0
Arsenic	0.002	0.05
Barium	0.19	1.0
Cadmium	< 0.003	0.01
Chromium	< 0.029	0.05
Silver	< 0.005	0.05
Lead	0.004	0.05
Mercury	< 0.0002	0.02
Selenium	0.005	0.01

As shown in the table, only iron and manganese concentrations exceeded MCL's. Water containing these elements may be objectionable to an appreciable number of people, but they are not generally hazardous to health. The high concentrations of iron and manganese may be related to incomplete filtering of the sample prior to analysis. Additional analyses of samples from the proposed test well will be required for confirmation.

Exploratory drilling at Site No. 2 was terminated at a depth of 80 feet without encountering ground water. The deeper aquifer may be present at the site, but it would probably be thinner than it is at Site No. 3.

CONCLUSIONS AND RECOMMENDATIONS

Exploratory drilling at three sites within the Park boundaries indicate that a test well drilled in the vicinity of Boring No. 3 should be capable of yielding about 100 gallons per minute. It may be possible to pump at higher rates for short periods of time, but the safe yield of the ground water reservoir would be exceeded. In any event, we recommend that ground water not be used for irrigation because of the limited supply available. Pumping at rates greater than 100 gpm would probably also induce migration of poor quality water that is present in the vicinity of the trailer park, and the old water well. Excessive pumping could also induce an upward flow of poor quality water that is present at depths below 200 feet. A water sample collected from Boring No. 3 indicated the presence of generally good quality water between the depths of 70 and 220 feet. The sample had a total dissolved solids concentration of 300 milligrams per liter (mg/l), considerably below the recommended maximum concentration limit of 500 mg/l for drinking water. However, the sample contained a fluoride concentration of 1.8 mg/l which is slightly above the recommended maximum contaminant level (MCL) of 1.4 mg/l. The sample also contained moderately high concentrations of iron and manganese which exceed MCL's. These two elements may be objectionable to some people, but they are not generally hazardous to health. In view of the only occasional use of ground water by Park visitors, the County could probably obtain a waiver of the requirements from the California Department of Health Services or the designated health officer for San Bernardino County.

The high iron and manganese concentrations could be related to incomplete filtration of the water sample from Boring No. 3 prior to analysis. In order to verify the concentration of these elements and test the yield of the aquifer, we recommend the construction of a test well at the site. The test well should be constructed to a depth of about 210 feet. In the event the water quality and tested well yields are acceptable, the test well can be completed as a production well at a modest additional cost. Proposed well construction details are shown on the following Figure 3. Technical specifications are presented in Appendix C. Prior to construction of the well, the County should verify that the well site is not within the Santa Fe Railroad right-of-way.

COMPLETION REPORT
CONSTRUCTION AND TESTING OF TEST WELL NO. 3
PARK MOABI, COUNTY OF SAN BERNARDINO

INTRODUCTION

This report presents a summary of drilling, construction and testing of Test Well No. 3 at Park Moabi, County of San Bernardino. All work related to construction of the test well was carried out during the period July 28, 1986 through August 12, 1986. Figure 1, Location of Wells, shows the location of the test well and other wells in the vicinity of the park.

The test well location was selected as the basis of information obtained from a previous exploration drilling program that was summarized in our report "Results of Exploratory Drilling" dated April 25, 1986. Historic records indicate that the aquifer penetrated by the well is not being utilized within the immediate area. The aquifer selected for development occurs between the depths of 70 to 210 feet below ground surface.

Well drilling and construction services were provided by Rottman Drilling Company of Lancaster, California. Well design, observation of test well construction, and testing were provided by LeRoy Crandall and Associates of Glendale, California.

Our professional services have been performed using that degree of care and skill ordinarily exercised, under similar circumstances, by reputable geologists practicing in this or similar localities. No other

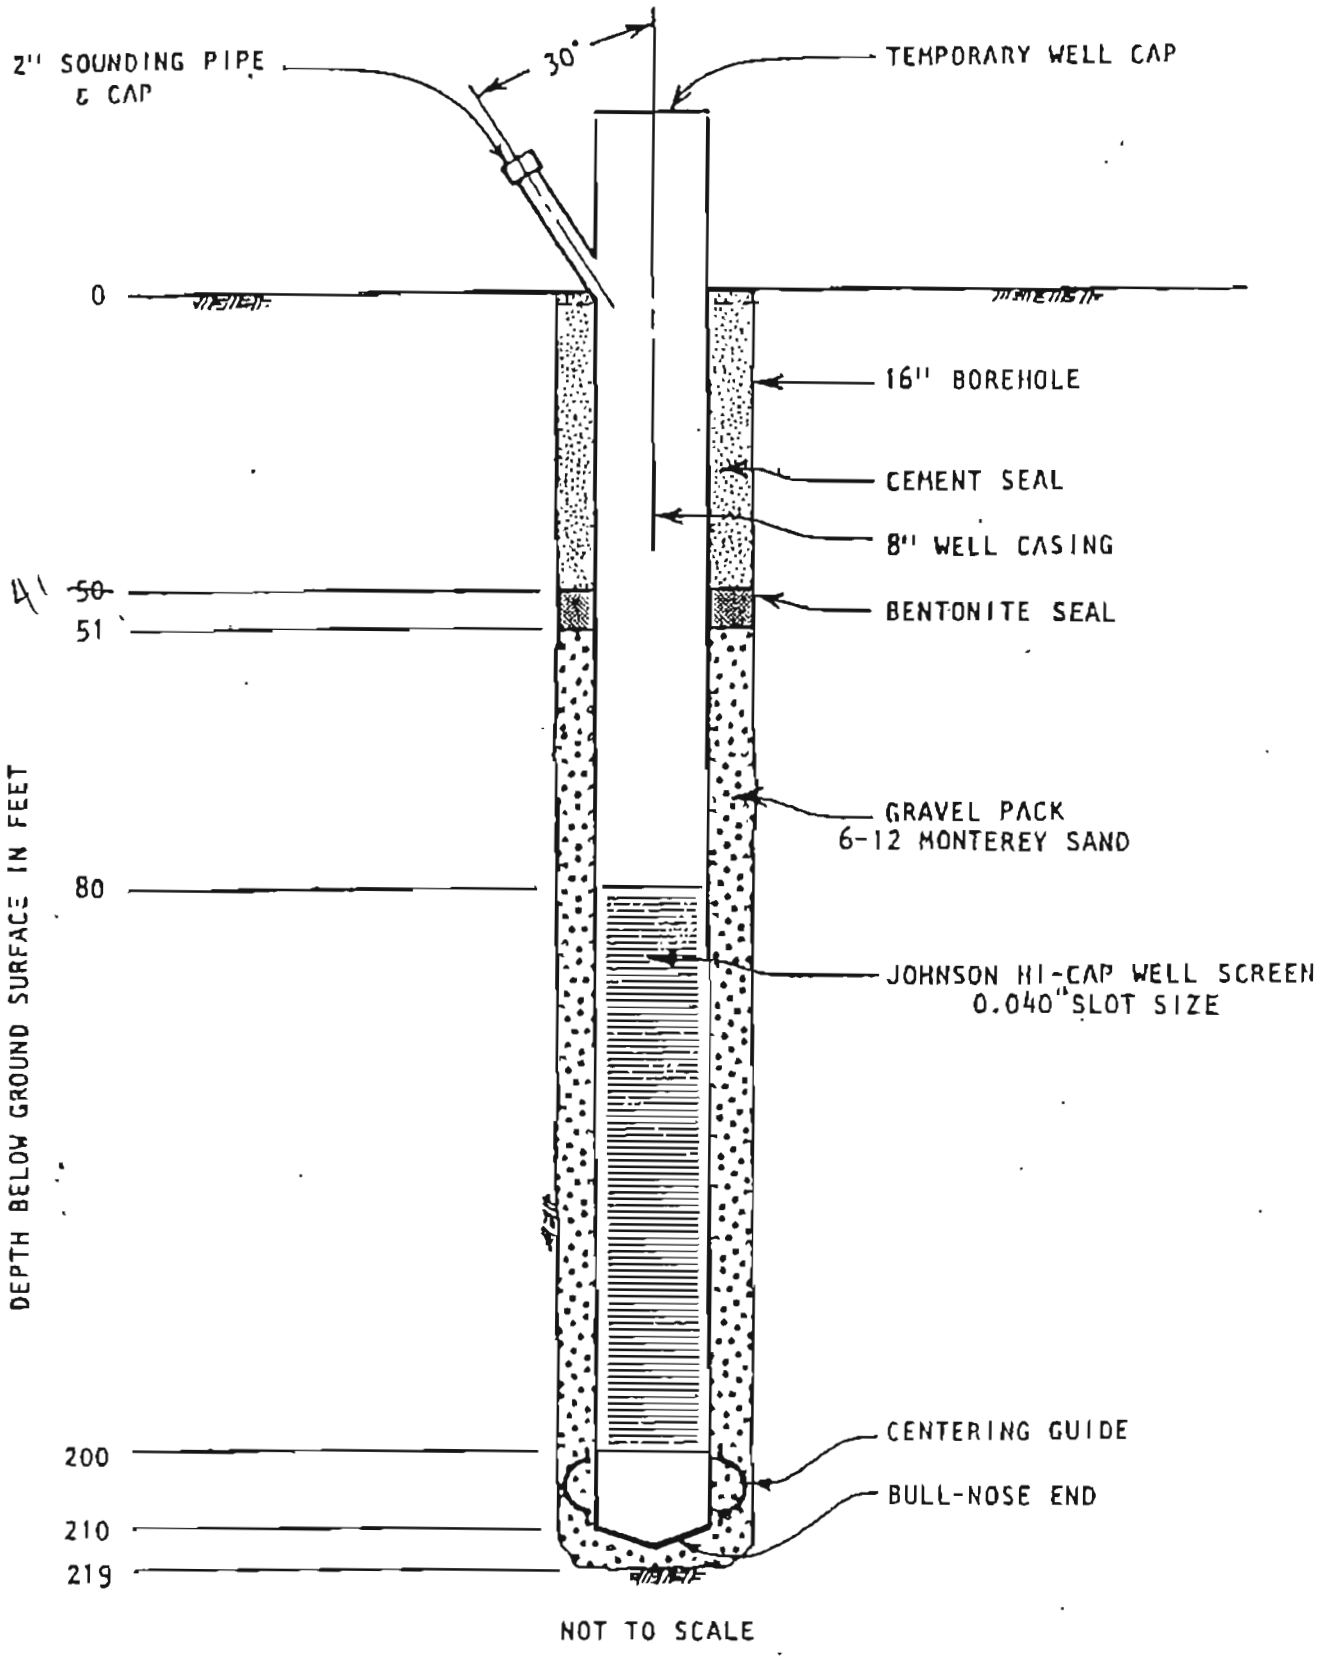
HYDROGEOLOGIC CONDITIONS

The lithologic log of Test Well No. 3 is presented in Appendix A. The materials penetrated by the boring consist of sandy gravel from ground surface to a depth of 35 feet. Silts and clays separate this unit from the underlying aquifer which yields water to the well. The aquifer is composed of sandy gravels to clayey gravels and occurs from 69 feet to depths greater than 250 feet. Field measurements of the electrical conductivity of water samples obtained during March 1986, between 90 to 210 feet, indicated the presence of good quality water which was subsequently confirmed by laboratory analyses presented in our report dated April 25, 1986.



TEST WELL CONSTRUCTION

Drilling of the well borehole commenced on July 29, 1986, by drilling a 12¼-inch-diameter pilot borehole to a depth of 220 feet. On July 30, 1986 through July 31, 1986, the pilot hole was then reamed to 16 inches to a depth of 219 feet. The borehole was drilled by the conventional rotary method using bentonite drilling mud to stabilize the borehole and to remove drill cuttings.

Following completion of the boring, an 8-inch-diameter casing was installed to a total depth of 210 feet. A Johnson hi-cap well screen was installed between the depths of 80 to 200 feet with a 10-foot sediment sump set at the bottom of the well between 200 to 210 feet. Well Construction Details are illustrated by Figure 2. Centering guides

JOB E-85417-C

FIGURE 2

PARK MOABI WELL NO. 3
WELL CONSTRUCTION DETAILS

were placed at 20-foot centers on the screened interval. The annulus between the borehole and well screen was packed with sieve size 6-12 Monterey sand while circulating clear water upwards through the annulus. A 10-foot bentonite slurry was placed on top of the sand filter through a tremie pipe from 41 to 51 feet. A concrete sanitary seal was installed after well testing was completed. The well was preliminarily developed by high velocity jetting until most of the colloidal and fine sediments were removed from the well.

A shaft-turbine test pump was then installed for further development and well testing. A Rossum sand tester was installed for measuring sand content. Development consisted of pumping and surging the well until the discharge became clear and sand-free. During the latter part of the development process, the sand content was less than 1 ppm, 20 minutes after surging.

The electrical conductance of well discharge was measured periodically during well development and testing. Conductance ranged from 1,300 micromhos/cm at the beginning of development and then declined to 820 micromhos/cm at the end of the testing.

WELL TESTING

Well testing commenced on August 6, 1986 and was conducted for a period of 24 hours. The well was tested using a shaft-turbine pump driven by a 150 horsepower diesel engine. The pump intake was set at 169 feet below ground surface. Discharge from the well was measured by a flowmeter that was periodically checked with a 5-gallon container. The test consisted of pumping the well at two discharge rates and

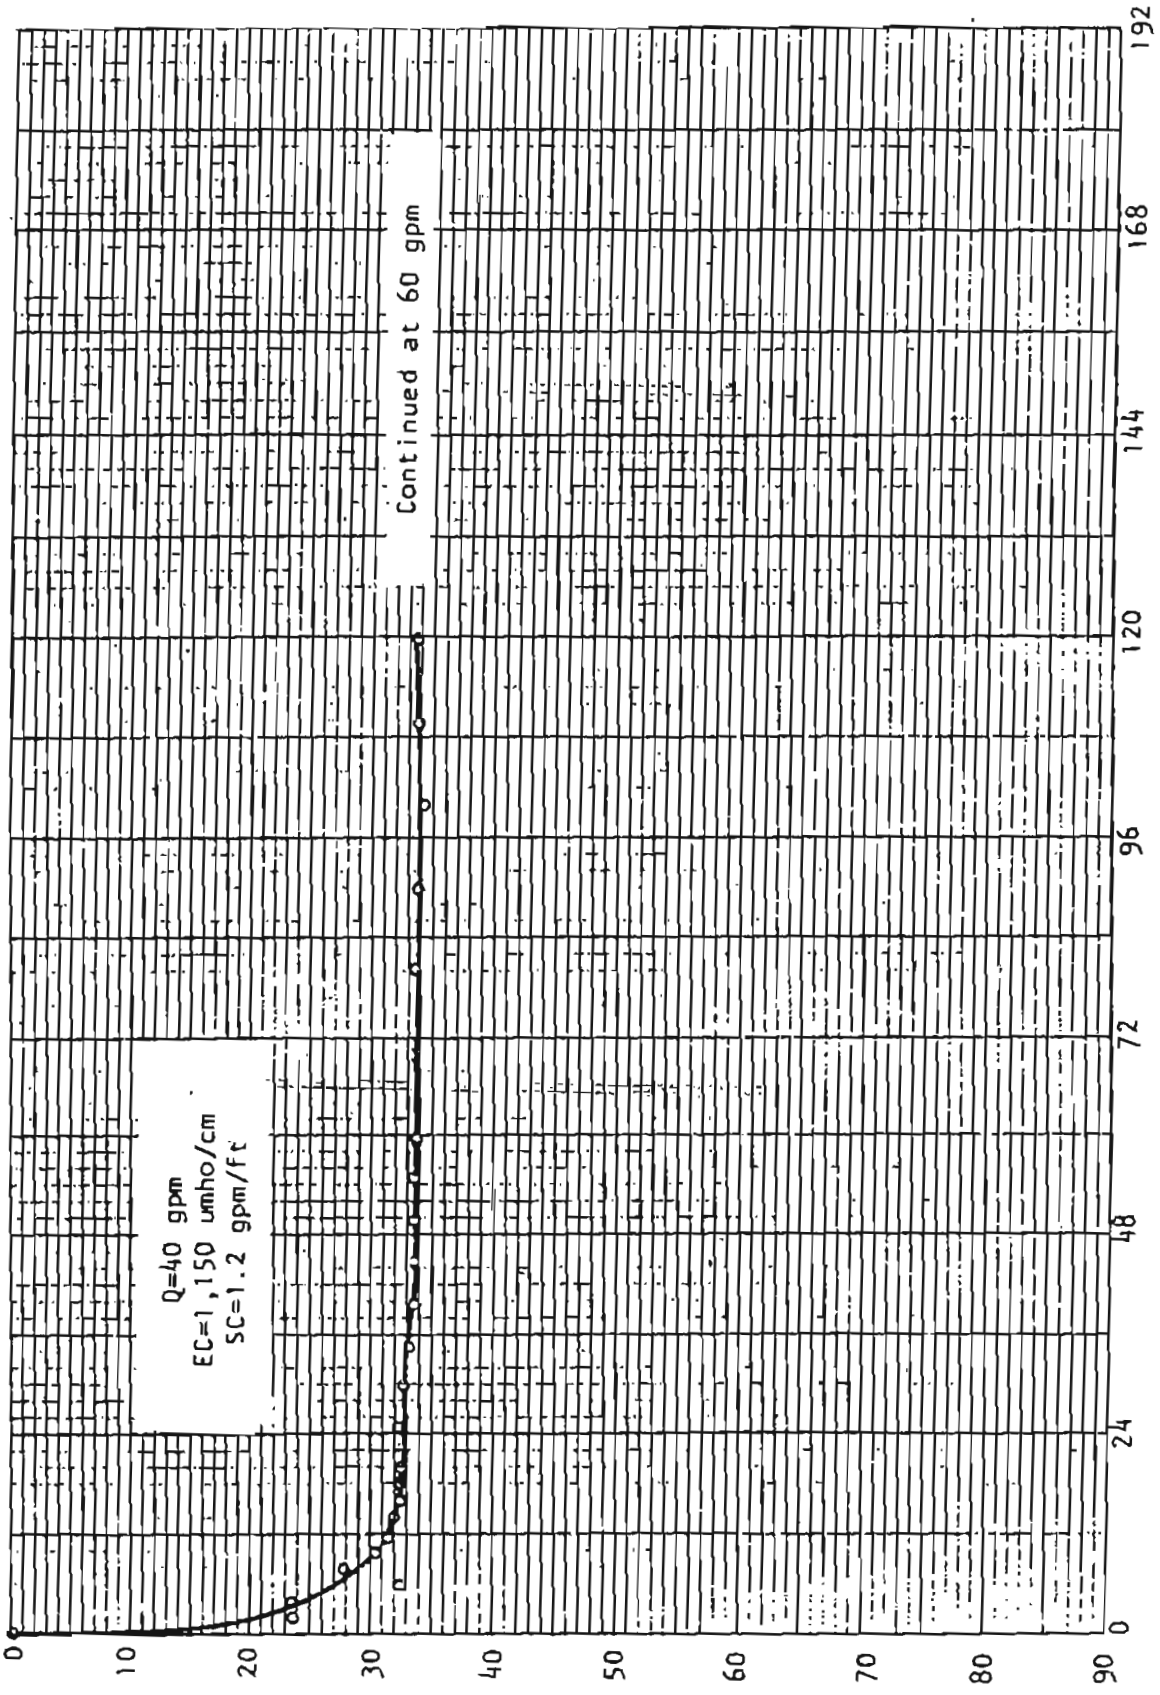
observing the water level drawdown in the well. Throughout the test, only traces of sand were measured in the Rossum sand tester. The following Table 1 summarizes test results.

TABLE 1

SUMMARY OF WELL TESTING

Discharge Rate gpm	Pumping Level Feet	Drawdown Feet	Specific Capacity gpm/ft	Electrical Conductance µmhos/cm	Sand Content ppm
40	87.18	33.60	1.19	1,150	<1 ppm
60	121.19	77.75	0.77	820	<1 ppm

At the end of the 24-hour period, the well discharge was increased to determine the maximum flow without breaking suction. This rate was found to occur between 67 to 70 gpm.



Water level measurements were made for 70 minutes after the pumping was stopped to determine the water level recovery rate. Recovery was found to be about 52 percent complete after 10 minutes and 96 percent complete after 70 minutes. Recovery measurements are illustrated graphically by Figure 5, Water Level Recovery.

GROUND WATER QUALITY

Previous chemical analyses of water samples from the test hole drilled at the site during March 1986 indicted that the site was underlain by alluvial materials containing a shallow sodium bicarbonate water and a deeper sodium chloride water. The shallow water sample had a

E-85417 -C

FIGURE 3

FIGURE 5

PARK MOABI TEST WELL 3

WATER LEVEL RECOVERY

total dissolved solids (TDS) concentration of 300 mg/l, while the deeper sample had a higher concentration of 780 mg/l.

Two water samples were collected during the August 1986 24-hour well pumping test for chemical analyses. The first sample was collected after pumping for two hours at a rate of 40 gpm. It had an electrical conductance of 1,140 micromhos/cm (about 740 mg/l TDS) and was sodium chloride in character. The salinity and chemical character of the discharge at this time were similar to that of the sample collected from the test well at a depth of 250 feet during March 1986. The salinity of the discharge diminished as pumping progressed and after 24 hours the TDS content declined to 490 mg/l. The chemical character at this time remained sodium chloride, but the chloride/bicarbonate ratio decreased. It appears that as pumping progressed, development of the well was continuing and a proportionally larger amount of bicarbonate water entered the well from the shallow portion of the aquifer.

With the exception of fluoride, chemical analyses of the water sampler collected from the well at the conclusion of the test indicate that it is suitable for drinking water. General mineral, physical and organic chemical analyses all indicated that constituent concentrations were below maximum contaminant levels (MCLs) prescribed by the California Health and Safety Code. However, the fluoride concentration was 1.8 mg/l, slightly above the recommended MCL of 1.4 mg/l. The elevated fluoride concentration probably would not be detrimental to the occasional Park visitor, but would not be suitable for the permanent

Park resident. This problem could be mitigated by providing the permanent residents with bottled water for drinking and culinary uses, or blending with water from the RO unit. The August 1986 sample had a Langelier Index of -0.12 which indicates water from the well has a corrosive tendency. The earlier March sample had a positive index and less of a tendency toward corrosion.

Chemical analyses of samples collected from the test well borehole during March and those collected during the well test are summarized on the following Table 2. Laboratory reports are presented in Appendix B.

RECOMMENDATIONS

Pump testing of Test Well No. 3 was carried out August 6 and 7, 1986 at rates of 40 and 60 gpm. The test indicates that the well should not be pumped at rates in excess of 60 gpm, preferable 50 gpm until long-term sustained yield can be determined after several months of pumping. It may be possible to pump at higher rates for short periods of time, but the safe yield of the ground water reservoir would be exceeded. In any event, we recommend that ground water not be used for irrigation because of the limited supply available. Pumping at rates greater than 60 gpm could also induce migration of poor quality water that is present in the vicinity of the trailer park and the old water well. Excessive pumping could also induce an upward flow of poor quality water that is present at depths below 200 feet.

TABLE 5

CHEMICAL ANALYSES OF WATER SAMPLES

Well Number	Date Sampled	EC x 10^6 at 25°C	pH	Mineral constituents in milligrams per liter											TDS in mg/l

Test Well 3 Pumping 120 min. @ 40 gpm	08-06-86	1,140		57	12	165			78	72	291	16.0			740*
Pumping 1,440 min. @ 60 gpm	08-07-86	790	7.9	42	9	111	5.3	0	84	49	172	3.4	1.9		490

*NOTE: (*) Estimated from EC.

The static water level in the well was 54 feet from ground surface. At a discharge rate of 60 gpm, the pumping level from ground surface may reach a depth of 145 feet after six months of continuous pumping. In view of the large drawdown anticipated, we recommend that the pump intake be set at a depth of 160 feet. Since motor cooling may be marginal, we recommend that a shroud be installed over the pump intake and motor to insure adequate cooling. Since the pump will be set within the well screen, nonabrasive (rubber) centering guides should be installed on the riser pipe at 20-foot intervals below a depth of 80 feet. We also suggest that a liquid level control system be installed. The low level cutoff could be set at 150 feet, and the high level start set at 80 feet.

After the well is placed in operation, static and pumping water levels should be made on a monthly basis. It would also be desirable to measure the electrical conductance on a monthly basis. The data obtained would be most useful in a future evaluation of the long-term yield of the aquifer.

Chemical analyses of the water sample collected at the end of the test indicate that, with the exception of fluoride, water from the well is generally suitable for drinking water. The sample was sodium chloride in character and had a total dissolved mineral content of 490 mg/l. Fluoride concentration was 1.8 mg/l which is slightly above the recommended maximum contaminant level of 1.4 mg/l. The slightly elevated concentration probably would not be harmful to the occasional Park visitor, but it would not be suitable for the long-term permanent

resident. However, they could be provided with bottled water for drinking and culinary uses. In view of the only occasional use of ground water by Park visitors, the County should ascertain if a waiver of the fluoride requirement can be obtained from the California Department of Health Services or the designated health officer for San Bernardino County.

Attention: Mr. Robert G. Wilkinson,
Project Manager

Gentlemen:

The attached report "Investigation of Potential Water Supply Sources for Park Moabi, San Bernardino County, California" describes the hydrogeologic and water quality conditions in the vicinity of Park Moabi. It also contains a description of various options that could be adopted to provide a long term water supply for the park. In the event you choose to adopt one of the options, we would be pleased to assist the County in implementing your decision.

Yours very truly,

PLATE 1

LOCATION OF WELLS

PARK MOABI

SAN BERNARDINO COUNTY, CALIF.

LeROY CRANDALL AND ASSOCIATES

BACKGROUND

Park Moabi is located along the west bank of the Colorado River about 10 miles southeast of Needles, California. The Park provides a variety of recreational activities including camping, boating and fishing. Water supply for the Park has been a continuing problem. Several attempts have been made to develop ground water, but all have been unsuccessful because of high ground water salinity. The locations of previously constructed wells are shown on Plate 1, Location of Wells.

At present, the Park obtains its water supply from an underground gravel collector (7N/24E-6B1) that has been constructed a few hundred feet from the River. However, pumpage from the collector well must be treated because of occasional bacterial contamination and the high mineralization that has ranged from 1,000 to over 2,000 milligrams per liter (mg/l). A reverse osmosis (RO) process is used to reduce the high mineralization to a level of about 200 mg/l. The RO plant is expensive to operate, and has only a capacity of about 40,000 gallons per day (gpd) which is inadequate to meet the park's peak demand of 80,000 gpd.

This report presents the results of our investigation of ground water conditions in the vicinity of the Park and the various options available for providing a long-term water supply. The investigation was authorized by the General Services Agency of the County of San Bernardino by Purchase Order J5078-M, dated December 19, 1985.

HYDROGEOLOGIC CONDITIONS

Park Moabi is located adjacent to the Colorado River at the foot of the Sacramento Mountains to the west and the Chemehuevi Mountains to the south. The mountain blocks are comprised of pre-Tertiary sedimentary, igneous and metamorphic rocks. These rocks underlie the Park at depths exceeding 1,000 feet, and probably are not capable of yielding an adequate water supply. They are overlain by a Miocene Fanglomerate comprised of cemented sand, gravel and silt. Water wells drilled in the vicinity of the Park have not penetrated the Fanglomerate, but elsewhere it has been reported to yield small to moderate supplies of water to wells. If present beneath the Park, it probably occurs at depths approaching 800 to 1,000 feet.

The Bouse Formation (Tb) of Pliocene age is exposed in the bluffs that rise several hundred feet above the River near the Park boundary and beneath most of the Park facilities at depths ranging from 0 to 100 feet. Locally, it is comprised of horizontally bedded clays, silts and fine sands that yield small quantities of water to wells. The Park Moabi Well No. 1 (7N/24E-6F1) penetrated the Bouse Formation at a depth of 44 feet. The well was constructed during March 1961. It is located adjacent to the Park maintenance building west of the trailer Park. The only lithologic log of rocks underlying the Park was recorded during the drilling of the well borehole. The log, which was published in the U.S. Geological Survey Professional Paper 486J, shows the following sequence of alluvial deposits.

Park Moabi #1
PM-01

SEQUENCE OF ALLUVIAL DEPOSITS

Description of Material	Thickness	Depth
Alluviums of Colorado River and its tributaries:		
Gravel, 3 in. to sand	22	22
Gravel, 2 to 8 in. rock	22	44
Bouse Formation:		
Clay	18	62
Shale	8	70
Clay, blue	32	102
Clay, gray, with rock	10	112
Rock, gray solid	6	118
Clay, gray, with rock	20	138
Clay, with softer rock	16	154
Rock, with clay	36	190

44 — 102
44
58

The log indicates the Bouse Formation at the well site is comprised of rather thick clay beds that would yield very little water. The well is reported to have yielded about 300 gpm, but well effluent contained excessively high concentrations of dissolved minerals that approached 3,000 mg/l. Other water wells north of the Park that have penetrated the Bouse Formation have also often yielded poor quality water.

Recent alluvial deposits (Qal) overlie the Bouse Formation. They are comprised of fine to coarse sands, gravels, and silts and are exposed throughout most of the flat-lying Park property, as shown on Plate 1, Location of Wells. Most of the water yielded by the Park Moabi Well No. 1 (7N/24E-6F1) was probably obtained form these deposits. The log of the borehole indicates they reach a depth of 44 feet at the well

site. They are probably much thicker several hundred feet to the north where surface runoff from the Chemehuevi Mountains is conveyed in a broad stream channel toward the Colorado River.

Recent sand dunes occur between the Park boundary and the River. They have little topographic relief and support a dense growth of native vegetation. The gravel collector and RO plant described previously are located within this area.

GROUND WATER DEVELOPMENT

Information on ground water development in the vicinity of the Park is limited to the incomplete construction records of four wells and one deep exploratory boring. The location of one of the wells, Park Moabi No. 2 (7N/24E-6X1) is unknown, but it apparently was never used because of the highly saline water it yielded. Construction details are summarized in the following Table 1.

Table 1
DESCRIPTION OF WATER WELLS

Well No.	Borehole Depth	Casing Depth	Casing Diameter	Perforated Interval	Capacity (gpm)
7N/23E-1M1 Abandoned	153'	86'	12"	Unknown	<5
7N/24E-6B1 Park Moabi	26'	26'	4'±	NA	
7N/24E-6F1 Park Moabi #1	190'	190'	10"	1 - 189'	300
7N/24E-6Q1 Test Hole	512'	None	None	None	Dry
7N/24E-6X1 Park Moabi #2	?	114'	10"	86 - 106'	430

Ground water for Park use is now obtained from a gravel collector located about 500 feet from the River. Construction details are not available, but it is reported to be about 300 feet in length which drains into a large diameter 26 foot deep sump. The sump is referred to as well 7N/24E-6B1 in Tables 1 and 2. Ground water is pumped from the sump to the adjacent RO plant where mineral concentration is reduced to about 200 mg/l at a production rate of 18 gpm. Storage is provided by an 80,000 gallon tank located near the Park entrance as shown on Plate 1.

Well No. 1 (T7N/24E-6F1) was constructed during March 1961. Well records are rather vague, but it apparently was constructed to a depth of 190 feet with perforations from 1 to 189 feet. The well is reported to have yielded 300 gpm with a drawdown of 12 feet from a static water level of 22 feet. If the records are valid, the well would have a moderately high specific capacity of 16 gpm/ft. When the well was tested during October 1961, the discharge had an electrical conductance ranging from 2,370 micromhos at the beginning of the test to 4,130 micromhos when the test was terminated after pumping 89 hours.

A test hole (7N/24E-6Q1) was drilled to a reported depth of 512 feet near the water storage tank. A small amount of water was encountered at a depth of about 150 feet, but the hole was dry when the total depth of 512 feet was reached. The test hole apparently only penetrated the Brouse Formation which is only known to yield small quantities of ground water.

An abandoned well (7N/23E-1M1) was constructed about one-half mile west of the Park during the 1970's to provide water for highway construction. Construction details are unknown, but the well is reported by the Park ranger to have yielded less than 5 gpm.

I-40 in 1965

GROUND WATER LEVELS

Ground water levels in water wells in the vicinity of the Park are related primarily to the elevation of the Colorado River, and have probably varied within a range of 10 feet. Water levels have not been systematically recorded, but recent measurements made during January 1986 show that the water table within the recent alluvial materials to have a northeasterly slope toward the River. January measurements indicate the depth to the water table ranged from about 16 feet at the RO plant to 89 feet at the abandoned well (M1) located west of the Park. At that time, the depth to the water table in the Park unused well (F1) was 23.3 feet.

WATER QUALITY

Water samples collected from the Colorado River between Davis Dam and Parker Dam indicate River water to be sodium sulfate in chemical character. During the period 1967-85 mineral concentrations ranged between 600 and 700 mg/l. It is generally suitable for drinking water with little treatment required. Water samples from the parks gravel collector surveys (B1) have been similarly sodium sulfate in chemical character, but samples have had electrical conductances ranging from 2,340 micromhos in 1961 to over 3,000 micromhos in 1977. Water from the

sump during this time would have an equivalent mineral concentration of 1,500 to 2,000 mg/l, which has required the costly removal of minerals before being used for domestic use. A recent sample collected during January 1986 had a rather low electrical conductance of 1,300 micromhos, which would be marginally suitable for drinking water. The source of high salinity water from the well is unknown, but it may be related to inflow from the embayment south of the well, decaying vegetation, or a consequence of leaching salts from alluvium and sand dune deposits in the vicinity of the well.

Water samples from the unused well (E1) have differed in chemical character and contained more dissolved minerals. They have been sodium chloride in character with electrical conductances ranging between 2,370 and 4,130 micromhos (equivalent to mineral concentrations of 1,540 and 2,680 mg/l). The source of the high salinity appears to be directly related to salts contained within the Bouse Formation. However, it could be partially related to decaying vegetation. Discharge from the well is reported to have had a hydrogen sulfide odor and an elevated temperature.

The best quality ground water in the vicinity of the Park occurs in the shallow alluvial deposits that traverse a large portion of the Park, and extend southwesterly toward the Chemehuevi Mountains. A January 1986 sample from the abandoned well (M1) east of the Park had an electrical conductance of 450 micromhos. A chemical analysis was not made, but ground water at the well site is probably sodium or calcium bicarbonate in character with a mineral concentration of about 300 mg/l.

RECOMMENDATIONS

Our investigation of ground water conditions in the vicinity of Park Moabi indicates that there are only two viable sources of long-term water supply:

1. The shallow alluvium that traverses the Park.
2. The Colorado River.

Plate 1 shows the location of two well sites that may yield good quality ground water. Site No. 1 is located near the existing RO plant well. The poor quality water at the site may be related to mineralization within the upper 20 to 30 feet of alluvium. If so, this zone could be sealed during well construction, which would permit the development of deeper good quality water. Since the site is near the RO plant, pipeline and power transmission costs would be minimized. Site No. 2 is located near the western Park property boundary. If the recent alluvial deposits at the site exceed 150 feet in thickness, it should be possible to construct a well capable of yielding about 100 gpm.

We recommend that exploratory drilling be undertaken at both sites before well design and construction is undertaken. Exploratory drilling should be undertaken using the dual-tube reverse air drilling method. This method permits the collection of point source water samples during the drilling process which is of considerable assistance in defining zones of poor quality water. If an adequate supply of good quality water is found to be present within the Park, a well design can

then be prepared for the preferred site. The cost of exploratory drilling should be relatively inexpensive, probably less than 20 percent of well construction costs.

Other options are related to the Colorado River diversions. It is our understanding that there are two programs being managed by the Bureau of Reclamation that permit taking water directly from the River. One program permits users to take water during years of excess flow. Under provisions of this program, the County could negotiate a contract with the Bureau to obtain the right to take water during the calendar year of 1986. The County could presumably continue to take water from the River during future years when excess flow occurs.

Another program under study by the Bureau would authorize participation in a project that envisions pumping seepage losses from the All American Canal in California, returning the losses to the canal, and establishing a credit for River diversions. This program is scheduled for implementation in 1988. The cost of participation would be based on the volume of water diverted, which has been estimated to range from $40 to $60 per acre foot, plus modest annual fees. Additional information on both programs can be obtained from:

Edward Hallenbeck, Regional Director
Lower Colorado River Region
U.S. Bureau of Reclamation
P.O. Box 427
Boulder City, Nevada 89005

Alden Briggs, Chief
Water Scheduling Branch
U.S. Bureau of Reclamation
P.O. Box 427
Boulder City, Nevada 89005
Telephone (702) 293-8677

We have not made an economic appraisal of the various options available to the County, but participation in one or both of the Bureau programs would probably be the least expensive. The County should also consider the cost of water treatment, as some will be required to meet drinking water standards. In view of the forecast water shortage, a decision to participate in the project to recover seepage losses from the All American Canal should include consideration of the Bureau's ability to implement the project on a timely basis.

In the event the County elects to proceed with ground water exploration and development, the services of LeRoy Crandall and Associates will be available for preparing technical specifications for exploratory drilling, water well construction, and the design of related facilities.

Engineering Evaluation of River Intake Structure/Fish Screen

Preliminary Engineering Evaluation of Colorado River Intake and Fish Screen

PREPARED FOR: Pacific Gas and Electric

PREPARED BY: CH2M HILL

DATE: 15 April 2012

Purpose and Scope

The purpose of this Technical Memorandum (TM) is to describe the Colorado River freshwater source alternative in support of the fresh water source evaluation for the Pacific Gas & Electric (PG&E) Topock Compressor Station (TCS) Basis of Design Report / Preliminary (30%) Design Submittal for the Final Groundwater Remedy. This evaluation included the following components:

- Identification of design criteria
- Development of site location evaluation criteria
- Identification of potential site locations
- Comparison and evaluation of potential site locations
- Conclusion

These evaluation components are described below.

Design Criteria

The selected groundwater remedy includes injection of freshwater to assist with flushing the plume through the treatment zone at a rate of 600 to 1,200 gallons per minute (gpm). Extracting water from the Colorado River as the source of this freshwater would require an intake structure and fish screen. Water from the intake would be pumped for treatment adjacent to the existing TCS freshwater storage tanks (Figure 1) then stored in new tanks prior to injection.

Intake Structure

The river intake would include a concrete structure, 12-inch intake pipe, a slide gate, and two submersible pumps, duty and standby, sized to deliver 1200 gpm.

Construction of the river intake structure would require a coffer dam at the base of the river bank to allow for dewatering of the work area. Further up the bank, construction would require trenching and/or a shoring system within the area excavated for the river intake structure. The coffer dam would be approximately ten feet by ten feet if constructed using sheet piles and the trenched area further up the bank could be as wide as 50 feet; the exact footprint of these construction areas would depend on the contractor's means and methods.

Fish Screen

The fish screen would also be sized to deliver 1200 gpm and designed to meet the California Department of Fish and Game (CDFG) and National Marine Fisheries Service (NMFS) fish screen design criteria for maximum approach velocity. Preliminary analysis indicates that a 30-inch diameter cylinder end of pipe type screen would work (Figure 2). The screen should have a minimum submergence of 1-foot below the river water surface elevation (WSE) and a minimum of 1-foot clearance from the screen to the river channel invert.

FIGURE 1
Potential River Intake and Fish Screen Locations

The screen unit would be an all stainless-steel unit using wedgewire screens with 50 percent open area. The wedgewire openings would also be sized to meet CDFG and NMFS fish screen design criteria. A baffled suction tube inside the screen will be used to support the screens and to distribute the intake flows uniformly across the entire screen surface. The screen cylinders will be cleaned using an automated brush cleaning system powered by a hydraulic power unit.

Source: http://intakescreensinc.com/projects/delta-cove/

FIGURE 2
Photographs of an End of Pipe Type Fish Screen

Operations and maintenance (O&M) activities would be minimal for an end of pipe type fish screen. Routine O&M would include a short weekly inspection similar to typical pumping facilities. Annual maintenance would include changing the oil filter on the power unit. The screen itself should be visually inspected when the river WSE is low; more frequent visual inspections would be required in areas where the debris exposure is high.

Site Location Evaluation Criteria

Evaluation criteria were developed to assess the feasibility of each potential river intake locations and to allow for comparison across the evaluated sites. The evaluation criteria fall into three main categories:

- Long-term siting
- Construction
- Permitting

Evaluation criteria are described below.

Long-Term Siting Criteria

Water Depth. As described above, the fish screen requires a minimum submergence of 1-foot below the river WSE to meet fish screen design criteria. Because the Colorado River WSE varies between 6 to 8 feet, the selected location must have sufficient depth at the lowest WSE.

Debris Protection. The fish screen should be located so as to minimize river debris damage potential.

Site Space Constraints. Sufficient space is required at top of bank (TOB) above the river intake and fish screen for a fence enclosure where the required cabinets, pumps, and other equipment can be located.

Operations and Maintenance Access. The river intake and fish screen must be accessible for long-term O&M activities.

Water Quality. Water from the river intake will have to be treated before it can be injected into the groundwater wells. Intake locations downstream of drainages and washes that enter the Colorado River and are known to experience high sediment loads after rain events will require more treatment to achieve water quality requirements.

Construction Criteria

Constructability. Issues impacting the constructability of the river intake and fish screen at a given site, particularly construction access.

Construction Impacts. Temporary impacts associated with construction, such as disturbed area.

Relative Cost. Comparative cost associated with the potential river intake and fish screen locations will be determined by proximity to the TCS storage tanks; the further from the tanks, the longer the pipeline.

Approvals, ARARs, and EIR Compliance

Visibility. The river intake and fish screen will be a visible addition and will require security and yard lighting.

Right-of-Way. Right-of-way (ROW) acquisition or easements may be required for construction or long-term O&M activities; depending on the property owner, obtaining the necessary rights could impede the project schedule.

Approvals/Compliance with ARARs and EIR.

Federal -- Compliance with substantive permitting requirements includes Section 404 of the Clean Water Act, Endangered Species Act (ESA) Section 7, and Section 10 River and Harbors Act.

State -- Compliance with substantive permitting requirements includes Section 1601 under the California Department of Fish and Game Code, California Endangered Species Act, Section 401 of the Clean Water Act, Clean Water Act Section 402 Construction SWPP, leases under State Lands Commission, etc. Additional consultation would be required if the project design included a log screen or upstream diversion structure to protect the intake from surface and submerged debris.

Potential Site Locations

Potential river intake locations are shown in Figure 1 and described below in Table 1. All locations are on the California side of the Colorado River. Photographs of each location are included in Attachment 1.

TABLE 1
Potential River Intake Locations
Freshwater Source Evaluation Technical Memorandum

Site No.	Location	Description
1	SoCal Gas Pipeline Bridge	Upstream of the natural gas pipeline and adjacent to the bridge structure located on the downstream edge of the project area.
2	Downstream of Arched Bridge	Just upstream from Site No. 1.
3	Historic Arched Bridge	On the bank upstream of the bridge.
4	North of Bat Cave Wash	Upstream of the Floodplain, downstream of the Moabi Regional Park Slough, and adjacent to the National Trails Highway (Historic Route 66).
5	Moabi Regional Park Peninsula	Upstream of the Moabi Park Slough.

It should be noted that some potential locations were not included due to identified fatal flaw(s). For example, there is a sand bar adjacent to the 20 Bench Floodplain that is exposed when the river WSE is low , making it infeasible to located the intake and fish screen along this section of river bank.

The area between the Arched Bridge and I-3 Pipeline Bridge was not evaluated. The Colorado River is shallow in this location and includes wetland type vegetation. Construction of a river intake and fish screen in this area would require significant disturbance of this vegetation in order to reach far enough into the river for the fish screen to have sufficient submergence during times of low WSE.

An intake and fish screen attached to the Arched Bridge was also not evaluated. While in theory this would minimize temporary construction and long-term impacts, this is not the case at this site. Steep slopes at the bridge would necessitate significant grading to facilitate site access during construction. Permanent vehicular access would need to remain after construction to facilitate O&M. O&M access would be particularly important as an intake and fish screen installed on a bridge pier is vulnerable to damage by river debris; a large log was seen caught against one of the Arched Bridge piers during a site visit.

Finally, the Arizona side of the Colorado River was not evaluated for a river intake and fish screen structure. River depths are not as great and turbidity is known to increase significantly following rainfall events along this side of the river.

Comparison and Evaluation of Potential Site Locations

Each site was compared and evaluated against the identified evaluation criteria as favorable, neutral, or unfavorable. This comparison and evaluation is summarized below in Table 2.

Site 5 was eliminated from further evaluation and not included in this analysis. A river intake and fish screen located at Site 5 would require constructing a pipe across or underneath the Moabi Park Slough in order to move water off the peninsula to the treatment facility. The slough is a navigable channel leading to a popular park. Therefore this is not a preferred site from a disturbance and compliance perspective.

TABLE 2
Comparison and Evaluation of Potential Site locations
Freshwater Source Evaluation Technical Memorandum

Evaluation Criteria	Site 1	Site 2	Site 3	Site 4	Comments
Water Depth	Favorable	Favorable	Favorable	Neutral	Sites with insufficient water depth are rated as unfavorable; sites with enough water depth are rated as neutral; sites with excess water depth are rated as favorable.
Debris Protection	Neutral	Favorable	Unfavorable	Neutral	Sites with limited debris protection are rated as unfavorable; sites with some debris protection are rated as neutral; sites with significant debris protection are rated as favorable.
Site Space Constraints	Unfavorable	Neutral	Unfavorable	Favorable	Sites with limited space are rated as unfavorable; sites with sufficient space are rated as neutral; sites with ample space are rated as favorable.
O&M Access	Neutral	Neutral	Unfavorable	Favorable	Sites with poor accessibility are rated as unfavorable; sites with sufficient accessibility are rated as neutral; sites with good accessibility are rated as favorable.
Water Quality	Unfavorable	Neutral	Neutral	Neutral	Sites with poor water quality are rated as unfavorable; sites with acceptable water quality are rated as neutral; sites with good water quality are rated as favorable.
Constructability	Neutral	Neutral	Unfavorable	Favorable	Sites with poor constructability are rated as unfavorable; sites with acceptable constructability are rated as neutral; sites with good constructability are rated as favorable.
Temporary Construction Impacts	Neutral	Neutral	Unfavorable	Favorable	Sites with significant temporary construction impacts are rated as unfavorable; sites with some temporary construction impacts are rated as neutral; sites with minimal temporary construction impacts are rated as favorable.
Relative Cost	Favorable	Favorable	Neutral	Neutral [a]	Sites with greater relative costs are rated as unfavorable; sites with average relative costs are rated as neutral; sites with less relative costs are rated as favorable.
Visibility	Unfavorable	Unfavorable	Unfavorable	Favorable	Sites with significant visibility are rated as unfavorable; sites with some visibility are rated as neutral; sites with sites with limited visibility are rated as favorable.
ROW	Unfavorable	Neutral	Neutral	Neutral	Sites with potentially significant ROW issues are rated as unfavorable; sites with manageable ROW issues are rated as neutral; sites with no ROW issues are rated as favorable.
Approvals and compliance with ARARs and EIR	Subject to consultation with Agencies	Subject to consultation with Agencies	Subject to consultation with Agencies	Subject to consultation with Agencies	Subject to consultation with Agencies.

[a.] It is assumed that water from the river intake and fish screen will be pumped for treatment adjacent to the existing TCS freshwater storage tanks. However, it is possible that freshwater from Site 4 could be treated directly adjacent to the river intake and fish screen structure. This would decrease the distance from intake to treatment and injection and, therefore, make the relative cost favorable.

Conclusion

Based on the above analysis, Site 4 appears to be a feasible location for a river intake and fish screen structure with the evaluation criteria being neutral or favorable. Easy site access at this location is a major driver of this result. Site 4 is close to the road and there is sufficient space at TOB for construction access and a fenced enclosure, which will minimize temporary construction and long-term impacts. It should be noted the applicable consultations and agency approvals will ultimately determine if Site 4 is feasible for a river intake and fish screen structure.

Model Updates (Prepared by ARCADIS)

MODEL UPDATES

Incorporation of Manganese oxidation

Manganese is naturally present in the soil at Topock in the form of insoluble Mn(III)/(IV) oxides. In actively reducing zones, manganese can be released into solution as Mn(II) via reductive dissolution of these Mn oxides. This process occurs naturally within the Topock floodplain, and it is expected to occur as a result of organic carbon injections during IRZ treatment of Cr(VI).

Once released into solution, the transport of Mn(II) within reducing environments will primarily be limited by sorption to mineral surfaces. This is expected to be the dominant mechanism controlling Mn transport within Topock downgradient of the IRZ and within the floodplain, due to sustained reducing conditions. Mn sorption is well-characterized using the surface complexation model approach (see discussion for arsenic sorption below), and sorption of Mn(II) has been incorporated into the Topock solute transport model to describe Mn transport downgradient of the IRZ and within the floodplain. Details on how Mn sorption was incorporated into the Topock solute transport model can be found in Appendix B of the 30% design document.

In less reducing environments at Topock, including the uplands and the alluvial aquifer beneath the floodplain, Mn(II) oxidation is expected to play a stronger role in the attenuation of aqueous manganese. Aqueous Mn(II) can be reoxidized biotically and abiotically in the presence of oxygen, resulting in precipitation. Abiotic oxidation of Mn(II) is slow, with a rate that is dependent on Mn concentration, dissolved oxygen concentration, and pH. For example, at pH 8 with a dissolved oxygen content of 2 mg/L (~25% air-saturation), the half life for Mn(II) oxidation is approximately 400 days (Morgan, 2005). Although abiotic oxidation of Mn(II) is slow, microbially-catalyzed oxidation of Mn(II) is much faster. Biotic oxidation of Mn has been studied extensively in the context of mining-derived pollution of streams, where Mn(II) oxidation can occur at the sediment-surface water interface, or hyporheic zone (Gandy et al., 2006, Harvey and Fuller, 1998; Kay et al., 2001). These results demonstrate that metal oxidation can be rapid, particularly at redox interfaces with active microbial consortia and an adequate nutrient supply. Harvey and Fuller (1998) studied the oxidation Mn(II) within the hyporheic zone of Pinal Creek, AZ. Oxidation rates were observed to be first order with respect to Mn concentration, with Mn(II) half lives between 0.7 and 8 hours. Laboratory work further confirmed these rates, while demonstrating the importance of solid:solution ratio (highlighting the combined role of mineral surface and microbial catalysis) and nutrient availability. Further work (Marble et al., 1999) demonstrated that these rates were independent of dissolved oxygen concentration above 30% saturation (~2.5 mg/L) and first-order with respect to oxygen below 30%.

Oxidation of Mn(II) was incorporated in the Topock solute transport model assuming a half life of 29 days. This value was obtained by starting with a first-order rate coefficient of 0.1 h^{-1}, representing the slowest rate observed by Harvey and Fuller (1998) at the Pinal Creek, AZ site, and scaling it back by two orders of magnitude to conservatively account for potential differences in nutrient status and microbial population. This rate was used to simulate Mn(II) oxidation in the uplands and beneath the floodplain, at interfaces where geochemically-reducing water (e.g., fluvial groundwater) contacts less-reducing water (e.g., alluvial aquifer with higher dissolved oxygen). At these interfaces, biotic oxidation of Mn will occur due to the presence of organic carbon and naturally-occurring microorganisms.

Updated Manganese solute transport modeling results

The 30% design simulated manganese transport in the solute transport model using only sorption as a mechanism to attenuate manganese migration throughout the solute transport model domain. This manganese sorption was utilized for both the naturally occurring manganese concentrations present in the reducing rind as well as manganese concentrations generated as a byproduct from IRZ's.

The solute transport model for manganese behavior was recently refined to incorporate oxidation as described in the section above. This manganese oxidation reaction was only simulated to occur in the uplands and in the deeper portion of the aquifer below the naturally occurring reducing zone. No manganese oxidation was simulated within the IRZ footprint, downgradient of the IRZ footprint, or within the naturally occurring reducing rind.

Figure 1 depicts the relative change in the manganese concentrations based on the original 30% design parameters and the recently refined manganese oxidation model with respect to manganese generated as byproducts from active insitu remediation after 30 years of simulated transport in model layer 1. The manganese distribution downgradient of the NTH IRZ and the TCS injection wells is identical between the two models because there is no manganese oxidation simulated in these areas. The primary difference in the manganese distribution in Figure 1 is evident in the uplands. This is due to the byproduct manganese extracted from the riverbank extraction wells and injected into the two upland inner loop recirculation wells. In the original 30% design model (left panel) the upland manganese distribution is significantly larger because manganese migration is only controlled by sorption. The refined manganese oxidation model (right panel) has a much smaller manganese distribution in the uplands due to active oxidation simulated in this area. Figure 2 depicts the same manganese model comparison after 30 years of simulated transport for model layer 3. The resulting distribution patterns in model layer 3 are similar to those presented in model layer 1, with the primary difference being the smaller manganese footprint in the uplands in the updated model due to manganese oxidation.

Figure 3 compares the relative change in the manganese concentrations based on the original 30% design parameters with the recently refined manganese oxidation model. The results are shown for layer 1 after 30 years with the naturally occurring manganese liberated in the reducing rind. There is no difference seen in Figure 3 (model layer 1) in the shallow aquifer within the footprint of the reducing rind because the same mechanism (sorption) is present in both model runs. In the Uplands injection area, where manganese oxidation has been incorporated in the recent model simulation, the manganese introduced in the uplands injection wells attenuates through oxidation minimizing the footprint.

The 30 year comparative results for model layer 3 are presented in Figure 4. Both panels depict the projected impacts of manganese sourced in the reducing-zone rind that has migrated or been injected into model layer 3, after 30 years of remediation. The panel on the left is the projection using the 30% design model; the panel on the right is from the updated model that incorporates manganese oxidation. The incorporation of manganese oxidation in this layer results in simulations that demonstrate a much smaller manganese footprint in Layer 3 of the model.

Incorporation of Arsenic adsorption

Downgradient of the IRZ, the arsenic released into solution due to the reductive dissolution of oxide minerals will attenuate via co-precipitation with iron oxide phases that form as Fe(III) reoxidizes. This process has been included in the Topock solute transport model by allowing aqueous arsenic to attenuate when organic carbon concentrations decrease below a threshold level. The arsenic attenuation rate was calibrated based on pilot test observations of arsenic transport. Further details on the incorporation of

arsenic co-precipitation within the solute transport model can be found in Appendix B of the 30% design document. This co-precipitation mechanism, however, is only relevant within redox “recovery” zones where dissolved Fe(III) is available for oxidation and precipitation. In other areas, the mobility of aqueous arsenic in groundwater is limited by adsorption to mineral surfaces. Both arsenate (As(III), which tends to be dominant in suboxic environments) and arsenite (As(V), dominant under oxidizing conditions) are known to adsorb strongly to mineral surfaces, particularly iron oxides (e.g., Dixit and Hering, 2003). Electrostatic attraction also plays a role in this adsorption process; at a pH below 9, the iron oxides which are positively charged, and attract dissolved species that are negatively charged (e.g., Appelo et al., 2002). The strong adsorption between iron and arsenic is due to a specific, “inner-sphere” binding mechanism, where oxygen ligands on arsenic displace surface hydroxyl groups on iron oxides. This particular reaction consumes protons, and is therefore more favorable at the lowered pH within and downgradient of the reducing zones. In this way, arsenic sorption is dependent on solution pH. For arsenate adsorption on iron oxide, the adsorption affinity decreases (i.e., less sorption) with increasing pH. The relationship is more complicated for arsenite, where sorption may increase or decrease with pH depending on solution conditions and mineralogy (Dixit and Hering, 2003).

Other species in solution, such as oxoanions (e.g., sulfate) and cations (e.g., Ca^{2+} and Mg^{2+}) can also compete with the sorption sites on iron oxide surfaces. These interactions have been studied extensively for iron oxides, particularly ferrihydrite. By quantifying adsorption interactions separately for different ions under different solution conditions, a combined model can be constructed that includes specific geochemical adsorption reactions for multiple species simultaneously, thereby accounting for the effects of pH and ion competition. This model is referred to as a surface complexation model (SCM).

It was assumed that As(V) (arsenate) would be the dominant species in the freshwater injection, given the oxidizing conditions of both the freshwater and the Upland groundwater. Ferrihydrite was assumed as the dominant adsorbent in the system; although ferrihydrite is not the dominant iron oxide mineral by mass, it is the dominant phase in terms of surface reactivity, given its very high surface area and sorption site density. Adsorption reactions were defined in the model using the SCM for ferrihydrite developed by Dzombak and Morel (1990). Estimation of surface site concentrations followed a procedure similar to that outlined in Appendix B of the 30% design. The groundwater chemistry (including pH, alkalinity, and major ion composition) used in the PHREEQC model was based on the average solution composition observed in monitoring well data within the freshwater injection zone. Arsenic adsorption was then incorporated into the transport model using a Freundlich isotherm, with the specific isotherm parameters calibrated using the SCM approach described above. The isotherm was calibrated by performing batch PHREEQC simulations with varying total arsenic content under site-relevant geochemical conditions.

Updated Arsenic solute transport modeling results

The original 30% design solute transport model simulated arsenic transport using arsenic precipitation in both the uplands and downgradient of the IRZ’s; no precipitation was simulated in the naturally occurring reducing rind. This conceptual model was based on the principal that under oxidizing conditions, arsenic will co-precipitate with mobile iron in groundwater. The primary mechanism governing arsenic migration downgradient of the IRZ’s is still co-precipitation with iron because iron will be mobilized with arsenic under IRZ induced reducing conditions. As the reducing conditions return to oxic conditions, the mobile arsenic will readily co-precipitate with the mobile iron. For the freshwater injection areas the arsenic/iron co-precipitation mechanism was replaced with the adsorption process described in the section above. In addition to the arsenic sorption mechanism, additional refinements were made to the updated model to reflect observed site data. These refinements included the incorporation of a background arsenic concentration of 2 ppb and a freshwater injection concentration of 15 ppb.

Figure 5 depicts the relative change in the arsenic footprint based on the original 30% design model (left panel) and the updated model (right panel) after 30 years of simulated transport in model layer 1. It is evident that the refined arsenic parameters result in a slightly larger arsenic footprint emanating from the freshwater injection wells relative to the precipitation only 30% design model. This is because there is no active mechanism to remove simulated arsenic from groundwater in the uplands, it only migrates at a slower velocity than the groundwater due to sorption. Both versions of the arsenic model indicate that any arsenic generated at the NTH IRZ or TCS injection wells is lower than 5 ppb after 30 years of simulated transport. Figure 6 depicts the comparative arsenic results for model layer 3 after 30 years of simulated transport. Similar to the model layer 1 results, the relative difference between the two models is apparent in the freshwater injection wells. The updated arsenic sorption model results in a slightly larger footprint than the original 30% design.

After 30 years of simulated active remediation, all of the remedial design elements were turned off to allow the system to return to ambient conditions. Figures 7 depicts the first year of simulated recovery (year 31) in model layer 1. These figures indicate that with the 30% design (left panel), arsenic concentrations will drop below 5 ppb within 1 year. The revised arsenic sorption parameter simulation (right panel) also shows a decreased arsenic footprint, it just retracts at a slower rate than the original 30% design. Figure 8 depicts the first year of simulated recovery in model layer 3. Similar to the model layer 1, the original 30% design arsenic distribution in layer 3 drops below 5 ppb after 1 year of recovery, while the updated model indicates a receding arsenic footprint.

Figure 9 shows the simulated arsenic results for the original 30% design and the updated model after 12 years of recovery (year 42) in model layer 1. The right panel showing the updated model results indicates that after 12 years of simulated recovery, only a trace amount of arsenic remains above 10 ppb, and the 5 ppb arsenic footprint has further decreased in size. Figure 10 shows the 12 year arsenic results for model layer 3. Similar to Figure 9, the model layer 3 results indicate the majority of the remaining arsenic concentrations are below 10 ppb, and the 5 ppb arsenic footprint is decreasing in size.

ALTERNATIVE FRESHWATER SOURCE SOLUTE TRANSPORT MODELING RESULTS

The solute transport model was utilized to evaluate the alternative freshwater source options considered within the 30% design. These included, the existing Havasu Natural Wildlife Refuge well (HNWR-1), a hypothetical new well(s) in Park Moabi, and the Colorado River. In order to reflect the appropriate freshwater source within the submodel domain, the regional groundwater model was run for each freshwater source individually and the submodel boundary conditions were extracted directly from the respective regional groundwater model run. The submodel thus reflects the associated hydraulic stresses induced by each freshwater source. Next, the solute transport model was run for each freshwater source with the following water quality parameters:

- chromium,
- arsenic,
- manganese associated with IRZ byproduct, and
- manganese associated with the naturally occurring reducing rind.

Figures 11 presents the chromium transport results for each of the three freshwater sources after 30 years of transport in model layer 1. The HNWR-1 source results are shown on the left panel, the Park

Moabi source results are shown in the center panel, and the Colorado River source results are shown in the right panel. This figure indicates that the different freshwater sources have a minimal impact on the solute transport results for the chromium plume. There is slightly more chromium mass remaining in the Park Moabi freshwater source scenario after 30 years than in the other scenarios due to a slightly lower hydraulic gradient. This would result in a slightly longer remediation timeframe for a Park Moabi well source. Comparing the results between the HNWR-1 and River freshwater sources indicates that these two sources result in nearly identical results for the transport and remediation of the chromium plume. Figure 12 depicts the chromium transport results for each of the three freshwater sources after 30 years of transport in model layer 3. Similar to Figure 11, the chromium mass remaining for each of the freshwater sources is very similar in model layer 3. This indicates that with respect to the chromium plume migration and remediation timeframe, the source of freshwater does not produce significantly different results.

Figure 13 presents the manganese byproduct transport results for the three different freshwater sources after 30 years of transport in model layer 1. The manganese solute transport run for all three freshwater sources incorporated manganese oxidation as per the updated manganese model described in the previous section. Figure 13 indicates that despite the three different potential freshwater sources, the manganese byproduct distribution downgradient of the NTH IRZ, downgradient of the TCS injection, and in the uplands are similar for all three scenarios. Figure 14 depicts the manganese byproduct results for model layer 3. Similar to the results for model layer 1, there were minimal differences between the three different freshwater sources.

Figure 15 presents the manganese in the naturally occurring rind transport results for the three different freshwater sources after 30 years of transport in model layer 1.The manganese solute transport run for all three freshwater sources incorporated manganese oxidation as per the updated manganese model described in the previous section. Figure 15 indicates that the three different potential freshwater sources result in very similar manganese distribution in the rind. Figure 16 depicts the manganese rind results for model layer 3. Similar to the results for model layer 1, there were minimal differences between the three different freshwater sources.

Figure 17 presents the arsenic transport results for the three freshwater sources after 30 years of transport for model layer 1. With respect to arsenic concentrations present in the freshwater injection wells, 15 ppb arsenic was utilized for HNWR-1 and Park Moabi, while only 2.6 ppb was utilized for the River source. While the exact arsenic concentration for Park Moabi is unknown, a value of 15 ppb was assigned as an approximate value to directly compare the impact to the HNWR-1 modeling results. Figure 17 indicates very similar arsenic impacts between the HNWR-1 and Park Moabi sources, with only a slightly biased northwest flow component observed at FW-INJ-2 due to the Park Moabi extraction. Arsenic concentrations for the River source remained below 5 ppb for the duration of the model at the freshwater injection wells. Figure 18 depicts the 30 year freshwater source analyses for model layer 3. Similar to the layer 1 results, the model layer 3 results indicate similar arsenic distributions between HNWR-1 and Park Moabi freshwater sources, while the river freshwater source remained below 5 ppb throughout the model domain.

Freshwater Injection Well FW-INJ-1

During the freshwater source analysis, the importance of well FW-INJ-1 (northeast freshwater injection well near the river), was evaluated. In the original 30% design, FW-INJ-1 was injecting at a rate of 100 gpm. In order to evaluate the impact FW-INJ-1 has on the chromium plume migration and remedial timeframe, as well as the impact on manganese and arsenic, the flow and transport models were run with FW-INJ-1 turned off. With respect to the chromium plume, there was no difference in simulated chromium

plume migration or remedial timeframe with FW-INJ-1 turned off. With respect to the manganese there was no difference in the manganese byproduct or rind without FW-INJ-1 operating. The only significant difference was with respect to the arsenic contained within the freshwater injection. Due to the limited benefit of FW-INJ-1 and agency comments regarding freshwater injection at this location, it is recommended to further analyze the FW-INJ-1 location as part of the 60% design process.

Responses to Comments

U.S. Department of the Interior Review Comments on the Freshwater Source Evaluation Technical Memorandum

DOI Review Comments and PG&E Responses

Comment Number	Comment Location (Section/Page/ Paragraph/Sentence)	DOI Comment	PG&E Response
1	General	The Freshwater Source Evaluation Technical Memorandum (FWTM) is responsive to comments #142 DTSC-55 through #153 DTSC-66. It represents considerable additional technical evaluation of the three principal sources for freshwater, and provides a sound basis for PG&E's selection the HNRW-1 well as the source for freshwater for use in the groundwater remedy when considering water quality and quantity, implementability and sustainability, and the influence of freshwater pumping on remedy performance. Additionally, based on the technical review of the modeling, DOI supports the premise that the arsenic in the water from the HNWR-1 well will result in minimal contamination of the aquifer and that the aquifer will return to background concentrations post-remedy.	Comment noted.
2	Section 2.2.1, Page 3, Total Dissolved Solids - 2nd para.	Can PG&E provide the geochemical model simulation performed using the U.S. Geological Survey's (USGS's) PHAST code that shows that less than one percent of the available porosity was blocked by reprecipitation? Also, this information is provided in Section 3.3.1 and is not directly applicable to Section 2.2.1 where the purpose is to only discuss the significance of TDS on aquifer plugging, not the specific analysis for HNRW-1.	The PHAST simulations were performed on a simplified model grid using average site hydraulic parameters, ambient water quality in the vicinity of the proposed injection area, and HNWR-1 water quality for injected water. These simulations are attached to this RTC table.
3	Section 2.2.2, Page 4, Total Dissolved Solids, 1st para.	Within this paragraph, there is discussion about groundwater in the lower portion of the aquifer reaching TDS of 10,000 mg/L. It also discusses low TDS in the upper portion. If the injection wells (UPGRAD-INJ-1 thru 4) are to receive both fresh water injection and carbon-amended floodplain water for reinjection, is it true that these wells can then only be screened in layers 3 and 4?	The injection wells need to be screened in all layers in order to effectively flush the plume through the IRZ. Water from the floodplain is currently planned to be delivered only to IRL-1 and IRL-2 (formerly UPGRAD-INJ-1 and 2); however, the design of all the injection wells will include screen throughout the saturated thickness of the aquifer.
4	Section 2.2.2, Page 5, Constituents Introduced Above Site Background …, 1st para.	There are no examples of the constituents that do not attenuate after the end of remediation. Does this pertain to emerging contaminants as covered in the next section?	Correct, this pertains to the emerging contaminants covered in the tech memo.

DOI Review Comments and PG&E Responses

Comment Number	Comment Location (Section/Page/ Paragraph/Sentence)	DOI Comment	PG&E Response
5	Section 3.1.1	As stated in the Technical Memo, groundwater extracted from HNWR-1 could be recharged from a number of different sources including the Colorado River. There is the potential that dissolved organic carbon (DOC) could be drawn into the aquifer supplying groundwater to HNWR-1. One scenario is that reactive DOC in groundwater causes reductive dissolution of iron and manganese oxides on aquifer sediment, resulting in an increase in the concentrations of Fe(II) and Mn(II). As(V) associated with these oxides could be released to solution and possibly reduced to As(III). If such a scenario occurs, groundwater from HNWR-1 injected into the upland aquifer could have greater concentrations of Fe(II), Mn(II), and As(III) or As(V) than were modeled for the Technical Memo. In addition, any DOC that has not reacted with aquifer sediment could be introduced into the upland aquifer. Because of the oxidizing nature of the upland aquifer, reoxidation of Fe(II) and precipitation iron oxides should provide additional sorption sites for any potential increase in As concentrations. The potential consequences of increased DOC in groundwater in the vicinity of HNWR-1 need to be discussed.	Although river water has been being pulled into the floodplain since 2005 in response to IM-3 pumping, the effects postulated in this comment have not yet been observed. It is possible that this could occur at HNWR-1 due to the higher pumping rate and likely different hydrogeologic conditions on the Arizona side of the river. Iron and manganese cause plugging in injection wells, even in relatively small concentrations. Any significant concentrations of iron and manganese in water from HNWR-1 would likely result in increased maintenance to the injection wells. Dissolved organic carbon (DOC) could also contribute directly to well plugging if it is in a form that can be readily metabolized by microbes. Frequent automatic backwashing of injection wells (included in 60% design) may be effective in preventing well plugging. However, depending on the concentrations of DOC and its form, additional treatment would likely be necessary to remove DOC prior to injection.
6	Section 3.1.1, Page 7, 1st para.	The conclusion should also mention that injected water withdrawn from wells at Park Moabi will likely be drawn back to Park Moabi by the end of the active remedial action.	This discussion was included in the discussion of freshwater supply in Exhibit 3.3-1 (Evaluation Criteria #1) of the 60% design document.

7	Section 3.3.1, and Attachment C, Page 3	Phreeqc simulations of arsenic mobility in the upland aquifer were conducted by adding As(V), at concentrations measured in groundwater from HNWR-1, to groundwater of the composition measured in the upland aquifer. The rationale for ignoring HNWR-1 groundwater chemistry should be explained. For example, is the volume of groundwater from HNWR-1 injected into the upland aquifer small enough so as not to alter the chemistry of the upland groundwater? Are the chemistries of both groundwaters similar?	Comment noted. The groundwater chemistry within the freshwater injection zone was used in the PHREEQC model because it was assumed that this chemistry will be most important in determining the long-term stability of adsorbed arsenate. After injection, and after the freshwater flows away from the injection point, the arsenic concentration in solution will be governed by equilibrium between sorbed arsenate and the native groundwater. Further, the average alkalinity and pH, two of the most important controlling factors for arsenate adsorption, are not substantially different between HNWR-1 and background alluvial groundwater. Although the TDS of HNWR-1 water is lower than in the native groundwater, the TDS of the injected water may increase slightly due to ion exchange and mineral dissolution. In addition, the effects of TDS on arsenate adsorption can be subtle and tend to partially cancel out (e.g., whereas ions may compete for arsenic sorption sites, adsorbed positively-charged ions can enhance the attraction of arsenate). PHREEQC tests using HNWR-1 chemistry and native groundwater chemistry suggest that differences in sorption are minimal. Note that as directed by DTSC on December 31, 2012, PG&E included a pre-injection treatment system in this 60% design. The decision by the State Water Resources Control Board (SWRCB) is anticipated to guide further direction from DTSC regarding the ultimate use of the freshwater source and what level of treatment if any will be required for various constituents. As such guidance is still forthcoming, in this 60% design BOD PG&E has made the conservative assumption for freshwater pre-injection treatment goals, specifically that the arsenic treatment goal is to reduce concentrations to below the federal/state Maximum Contaminant Level (MCL) of 10 micrograms per liter (µg/L) and that the fluoride treatment goal is concentrations below the state MCL of 2 milligrams per liter (mg/L). Therefore, as the freshwater source will be treated for arsenic, the fate and transport of naturally occurring arsenic associated with freshwater injection is no longer applicable and has been removed from the 60% design.

DOI Review Comments and PG&E Responses

Comment Number	Comment Location (Section/Page/ Paragraph/Sentence)	DOI Comment	PG&E Response
8	Section 3.3.1, Page 12, 2nd full para.	The Technical Memo states that amorphous iron oxide having sorption properties measured by Dzombak and Morel (1990) where used to define the concentration of sorption sites in the upland aquifer. Amorphous iron oxide is usually associated with iron oxides that have precipitated more recently. Over time, amorphous iron oxides tend to recrystallize forming iron oxide minerals such as goethite which can have different sorption characteristics than amorphous iron oxides. The evidence for using amorphous iron oxides as the adsorbent for arsenic needs to be discussed.	The concentration of sorption sites was estimated using measured amorphous iron oxide concentrations in aerobic core study samples (CH2M HILL 2005a, as referenced in this TM), along with published properties of adsorption sites per unit mass of amorphous iron oxides. The method of measurement referenced from the Aerobic Core Study was Dithionite-Citrate-Bicarbonate, which selectively measures amorphous iron (as opposed to crystalline forms such as goethite).
9	Section 3.3.1, Page 12, 2nd full para.	State the thermodynamic database used in the Phreeqc modeling (Wateq4f).	Wateq4f was not the database used in the PHREEQC modeling. The default PHREEQC thermodynamic database was used in geochemical calculations (Parkhurst and Appelo 1999 as cited in the TM), supplemented with parameters for arsenate adsorption on iron oxides obtained from Dzombak and Morel (1990). Note that as directed by DTSC on December 31, 2012, PG&E included a pre-injection treatment system in this 60% design. The decision by the SWRCB is anticipated to guide further direction from DTSC regarding the ultimate use of the fresh water source and what level of treatment if any will be required for various constituents. As such guidance is still forthcoming, in this 60% design BOD PG&E has made the conservative assumption for freshwater pre-injection treatment goals, specifically that the arsenic treatment goal is to reduce concentrations below the federal/state MCL of 10 µg/L and that the fluoride treatment goal is concentrations below the state MCL of 2 mg/L. Therefore, as the freshwater source will be treated for arsenic, the fate and transport of naturally occurring arsenic associated with freshwater injection is no longer applicable and has been removed from the 60% design.
10	Section 3.3.1, Page 12, last full para.	The oxidation state of arsenic used in the Phreeqc modeling needs to be stated. Under oxidizing conditions, arsenic +5 [As(V)] is stable; under reducing conditions, arsenic +3 [As(III)] is stable. Each oxidation state of arsenic has different sorption characteristics. A brief explanation of the HNWR-1 modeling results would be useful. For example, 'groundwater from HNWR-1 is oxidizing as indicated by the presence of dissolved oxygen. Phreeqc modeling of groundwater chemistry from HNWR-1 indicates that As(V) is the stable oxidation state of arsenic.'	The oxidation state of arsenic was not specified for the input to PHREEQC. The program uses the specified redox characteristics of the system to calculate the proportions of As(V) and As(III). In the environment surrounding the injection wells (and in HNWR-1), the As is predominantly As(V). The PHREEQC database contains separate adsorption criteria for each oxidation state of arsenic.

DOI Review Comments and PG&E Responses

Comment Number	Comment Location (Section/Page/ Paragraph/Sentence)	DOI Comment	PG&E Response
11	Section 3.3.1, Page 12, last full para.	The explanation regarding the stability of dissolved arsenic is adequate but it is not apparent that a simple model of a complex hydrogeologic system could explain difference in arsenic concentrations that only range approximately a factor of 2 or 3 and are at very low levels. As stated in discussions, groundwater monitoring is needed to determine the fate of As in the uplands and to determine the appropriate corrective action as deemed necessary.	As directed by DTSC on December 31, 2012, PG&E included a pre-injection treatment system in this 60% design. A monitoring plan is also included in Volume 2 of the Draft O&M Manual. As previously mentioned, the decision by the SWRCB is anticipated to guide further direction from DTSC regarding the ultimate use of the fresh water source and what level of treatment if any will be required for various constituents. The freshwater source details will be included in an addendum to this 60% design, after such requirements are determined and completion of planned source water studies.
12	Section 3.3.1, Page 13, 2nd complete para.	Arsenic in well TLMP-2 is relatively low and it is in the geothermal groundwater. Simply based on the distribution of arsenic concentrations, it appears that something in the hydrogeologic environment from HNWR-1 to PGE-95 is causing arsenic concentrations to be higher than elsewhere on the Arizona or California side of the river. It may be related to geothermal water, but it seems apparent that some other factor(s) is causing the high arsenic concentrations.	Agreed. It is not clear exactly what factors contribute to the elevated arsenic concentrations in the area near HNWR-1 and PGE-9S.
13	Section 3.3.1, Page 14, 3rd complete para.	This new assessment of the limited amount of water sourced from the Sacramento Wash is a significant finding of this TM and implies likely changes to the TDS of the water being withdrawn overtime, particularly since there are shallow high TDS environments nearby (MW-54-85). A backup plan (as suggested) for additional wells to the north should be developed. One of the potential considerations regarding the long term pumping of the HNWR-1 well is that arsenic concentrations could be reduced over time as drawdown pulls from areas of less geothermal activity. If an addition pump test is planned, it is recommended that As be sampled both before and after pumping.	A contingency well site has been identified north of HNWR-1 and is shown and discussed in Section 3.3.2 of the 60% design. A long-term pump test is being planned for HNWR-1 (as part of the Alternative Freshwater Source Evaluation Implementation Plan, currently under review by DTSC and DOI) that will include sampling for As and other constituents prior to and throughout the pumping period to look for any trends in arsenic and other constituents.
14	Section 3.3.1, Page 17, 1st bullet	Manganese dioxide implies a greensand filter which is used to oxidize iron and arsenic causing precipitation and removal. However, iron and arsenic has been oxidized already. It appears it is being used for its adsorption capacity.	Manganese dioxide media has higher adsorptive capacity and is a very durable media.

DOI Review Comments and PG&E Responses

Comment Number	Comment Location (Section/Page/ Paragraph/Sentence)	DOI Comment	PG&E Response
15	Section 3.3.1, Page 19	It is assumed that the treatment of all the HNWR-1 water was considered in the estimate of the facility size. If blending of HNWR-1 treated water and untreated water were considered, couldn't the facility size be reduced?	Correct, the size of the arsenic treatment system depicted in the Tech Memo was based on assumptions regarding influent arsenic concentration (15 µg/L), treatment process (capable of achieving 5 µg/L), and effluent arsenic concentration (5 µg/L to provide a factor of safety below the MCL). There would be no size reduction since blending water with 15 µg/L arsenic with treated water with 5 µg/L arsenic to achieve effluent of 5 µg/L arsenic, would require treatment of all water. A bench-scale test is currently being conducted to optimize system processes/design which might result in a smaller overall footprint. Results from the bench-scale were incorporated into the 60% design (see the Freshwater Pre-Injection Treatment System Design Basis Technical Memorandum included in Appendix M of this 60% BOD). Additional information from the ongoing testing will be included in the addendum of the 60% design.
16	Section 3.3.2, Pages 20-21	No data is included for arsenic for the California well(s). Data, if available, should be provided for the California well(s) for comparison.	Arsenic data for California wells PM-03 and PM-04 were included in Tables 3-4 and 3-5 of the Freshwater Source Evaluation Technical Memorandum, respectively.
17	Section 3.4.1, Page 27, Initial Design	Management of Quagga Muscles should be included as a consideration for river water intake structures.	Approaches to prevent quagga mussel attachment or growth fall into two categories, non-chemical and chemical control. Typically, several control approaches are implemented together as part of an overall control strategy based on a host of design criteria. Example control approaches are: • Removal/cleaning/replacement of screen • Physical removal • Filtration • Chemical treatment • Application of either an anti-fouling or biocide coating In summary, quagga mussel management will have additional impacts to the infrastructure required (e.g., footprint size, pre-treatment, and intake structure design) as well as O&M of the fish screen (e.g., recoating, chemical delivery and storage, and additional process piping and pumping). A more detailed analysis would be required to find the optimum control strategy.

18	Exhibit 3-11, Contingency Matrix, Page 37, Item 4.	If arsenic is more mobile than expected in the upland aquifer, another possible contingency measure would be *in situ* treatment of arsenic. Iron could be added to the injected groundwater, thereby increasing the number of sorption sites in the aquifer. Fe(II) added to the aquifer would be oxidized by dissolved oxygen in groundwater resulting in precipitation of amorphous iron oxide. Fe(II) would likely disperse into the aquifer before oxidation and precipitation minimizing any change in permeability. Fe(III) could also be added; however, there is the potential problem of more rapid precipitation near the well screen causing decreased permeability.	As reported in the Freshwater Tech Memo, PG&E reviewed a pilot test of in-situ arsenic treatment involving ferric iron. The process required considerable above-ground treatment infrastructure and the wells in this pilot test plugged in a matter of hours. It is possible that an in-situ arsenic treatment scheme could be made to work, but it would likely require a pilot scale test to develop the technology prior to full scale application. As directed by DTSC on December 31, 2012, PG&E included a pre-injection treatment system in this 60% design. The decision by the SWRCB is anticipated to guide further direction from DTSC regarding the ultimate use of the fresh water source and what level of treatment if any will be required for various constituents. The freshwater source details will be included in an addendum to this 60% design, after such requirements are determined and completion of planned source water studies.

California Department of Toxic Substances Control Review Comments on the Freshwater Source Evaluation Technical Memorandum

DTSC Comments and PG&E Responses

Comment Number	Comment Location (Section/Paragraph/ Page)	DTSC Comment	PG&E Response
1	General Comment regarding arsenic in HNWR-1	Based on California State Water Resources Control Board's anti-degradation policy, discharge of arsenic from Arizona above the background for the receiving water body will require a Waste Discharge Requirement. Currently this issue is being discussed by the agencies and PG&E. DTSC understands that PG&E can consider in-situ or ex-situ arsenic pre-treatment prior to injection with technologies discussed in the Tech Memo. However, PG&E should recognize such action to be a disadvantage in the use of the HNWR-1. Currently, PG&E concludes that pre-treatment is not necessary; therefore, it is an advantage for the use of HNWR-1. Another disadvantage to the use of the HNWR-1 is that modeling indicates, at a minimum, an additional 12 years would be necessary for the injected arsenic concentration to significantly attenuate. This adds time to the remedy to be completed. Additional monitoring infrastructure would also be required and for a longer period of time to adequately monitor for arsenic. Finally, if arsenic does not behave as modeled, a potential exists for a separate action to cleanup arsenic around the injection areas. Impacts associated with importing arsenic bearing water from HNWR-1 have been modeled based on preliminary assumptions. It might become necessary to increase HNWR-1 injection rates into the upland areas to contain the plume. If so, would there be additional impact associated with the imported arsenic? Similarly, it may be necessary to install additional injections wells to ensure contaminated groundwater does not improperly migrate to the west or north. This would also result in a larger arsenic contaminant footprint. Finally, it may be advantages to increase flow HNWR-1 flow rates to increase cleanup time. While HNWR-1 contains arsenic above regulatory criteria, it will continuously burden remedy decisions now and in the future.	The well network being designed for monitoring water quality near the injection wells during the active phase of the remedy will be adequate for monitoring arsenic following cessation of injection. If the arsenic behaves as expected and does not migrate more than a few hundred feet from the injection wells during the active phase of the remedy, there is no reason to think it would migrate further after the injection stops. Therefore, the post injection monitoring would likely consist of sampling the inactive injection wells and possibly a few nearby monitor wells to confirm that arsenic is not moving and concentrations are declining. It will not require any additional infrastructure and will likely only require a minimal amount of monitoring. As directed by DTSC on December 31, 2012, PG&E included a pre-injection treatment system in this 60% design. The decision by the SWRCB is anticipated to guide further direction from DTSC regarding the ultimate use of the fresh water source and what level of treatment if any will be required for various constituents. The freshwater source details will be included in an addendum to this 60% design, after such requirements are determined and completion of planned source water studies.
2	2.1 Water Quantity, Page 2	The section states, "*If the aquifer is more transmissive than anticipated in these areas, additional fresh water would be needed to create the gradient necessary for remedy operation. On the other hand, if the aquifer is less transmissive than anticipated, less water would be needed."* The process for changing the injection rate should be include in the Operations and Maintenance Plan and must allow for communication with agencies and approval.	The injection wells will be tested after installation and if hydraulic properties are different than anticipated, additional model simulations will be conducted to evaluate the effect on the design. This process is described in Section 3.3.3.4 of the 60% BOD.

DTSC Comments and PG&E Responses

Comment Number	Comment Location (Section/Paragraph/ Page)	DTSC Comment	PG&E Response
3	2.2.1 Prevention of Well and Aquifer Plugging, Total Dissolved Solids, Page 3	Aquifer plugging occurring at the IM-3 injection well(s) must be discussed as it is a site specific example of aquifer plugging that occurs within the exact area of the remedy. Such site specific knowledge cannot be overlooked. The mechanism(s) for clogging in IM-3 wells should be discussed and compared to model runs. Does the model perform adequately when compared to plugging/reduced well efficiency at IM-3 injection wells?	Reduced performance of IM-3 injection wells has been observed periodically over the last several years. The incrustation on the well screens has been identified as a thin layer of manganese oxide, and thermodynamic calculations using PHREEQC have identified manganese mineral phases that are at or above saturation in the injection water. The precipitation kinetics for these compounds are varied, making it difficult to precisely predict how quickly and how much manganese will precipitate, but observations indicate that production drops when manganese is above 10 µg/L in the injection water. A manganese impurity in the ferrous chloride used by the treatment plant is suspected to be the source of manganese causing the precipitation. Due to uncertainty in the kinetics of manganese precipitation and lack of sufficient data on the concentrations of manganese in the effluent during much of the IM-3 operational history, modeling of the IM-3 well plugging due to manganese would not provide any additional confidence in the geochemical model. The desired water quality goal for manganese included in the freshwater tech memo (<10 µg/L) is based on recent experience with well plugging during operation of the IM-3 wells. It has been observed that the IM-3 wells perform much better when Mn concentrations in the injected water are <10 µg/L. Thus, the site specific IM-3 experience has been incorporated into the Freshwater Tech Memo.
4	2.2.1 Prevention of Well and Aquifer Plugging, Dissolved Organic Carbon Solids, Page 3/4	PG&E states that "*the average dissolved organic carbon content in the Colorado River near* *Topock is 9 mg/L. While this is considered low for a surface water source, it is considerably higher than the groundwater sources being considered and might be enough carbon to contribute to injection well fouling*." Can river water be tested now to determine if treatment to prevent well fouling is needed? Does data already exist in MWD databases for a proper assessment?	There are no existing data to support an evaluation of the plugging potential the dissolved carbon in the river water. Laboratory microcosm tests could be conducted at any time to evaluate the bio-availability of the dissolved carbon in the river. A microcosm test would provide a basis from which to estimate plugging potential, but might not provide definitive results about the need for a treatment plant. A pilot test using an injection well at the Topock site would be the best means of evaluating plugging potential of organic carbon in river water.

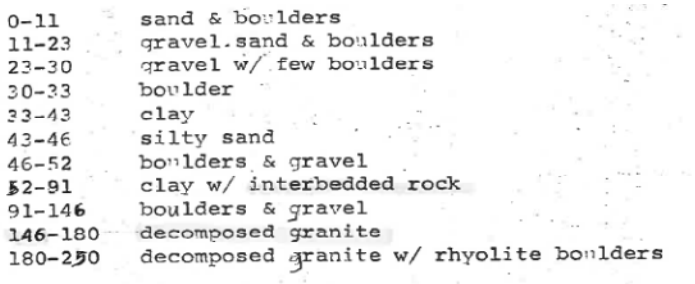
5	2.2.2 Protection of Aquifer Water Quality, Page 4	According to the RWQCB anti-degradation policy (State Water Resources Control Board Resolution No. 68-16), injection of arsenic above MCL outside of the current plume into a receiving body that has lower concentration would not meet ARAR for anti-degradation. Although PG&E is still evaluating this matter, a potential for schedule delay exists if a pre-treatment system would prove to be necessary. To avoid a potential significant schedule delay, it is recommended that PG&E include the location and design of this hypothetical arsenic pre-treatment system in the 60% Design as it may be required to comply with RWQCB requirements. The section states, "During the Topock Background Study, arsenic concentrations above the MCL were found in water supply wells in the vicinity of the Topock Marina, Arizona." Figure 3-6 of the Tech Memo includes an arsenic concentration map developed from the background study. It unfortunately indicates that the Arizona well is located in an area of some of the highest arsenic concentrations in the entire region.	As directed by DTSC on December 31, 2012, PG&E included a pre-injection treatment system in this 60% design. The decision by the SWRCB is anticipated to guide further direction from DTSC regarding the ultimate use of the fresh water source and what level of treatment if any will be required for various constituents. The freshwater source details will be included in an addendum to this 60% design, after such requirements are determined and completion of planned source water studies.

DTSC Comments and PG&E Responses

Comment Number	Comment Location (Section/Paragraph/ Page)	DTSC Comment	PG&E Response
6	2.2.2 Protection of Aquifer Water Quality, Constituents Introduced Above Site Background or Above Water Quality Standards that Do Not Attenuate After the End of Remediation, Page 5,	The section states, "*As discussed above, modeling indicates that arsenic concentrations that may temporarily be elevated by injection of HNWR-1 well water (with naturally occurring arsenic level of 15µg/L, which is below site background of 24.3µg/L but above the MCL of 10µg/L) will attenuate under site conditions and return to pre-remedy baseline levels after the end of remediation (see Figures 3-9 through 3-12). Monitoring will be performed during remedy implementation to verify the above modeling results, and appropriate adjustments will be made to remedy operations as needed.*" This paragraph does not portray arsenic issues in an appropriate light. Arsenic modeling results pictured in Figure 3-12 yields, upon close examination, that elevated arsenic concentrations, including values above the MCL, will still persist at least 12 years after the outboard injection of water ceases. Therefore, it must take even longer for arsenic levels to revert to pre-remedy, baseline conditions. See other arsenic comments regarding RWQCB's anti-degradation policy; long term arsenic persistence and, therefore, long term monitoring requirements. Furthermore, the 24.3 µg/L arsenic value cited in the paragraph is a regional value and not site specific. DTSC commented on this very issue during development of the background study report. PG&E needs to site language from the 2009 background study report acknowledging limitations with the regional values. The next paragraph states, "*It should be noted that naturally occurring chromium (VI) in the fresh water used for injection will be at concentrations at or below the site background of 32µg/L. Any residual Cr(VI) introduced with the fresh water is expected to be persistent in the aerobic portions of the aquifer, but would continue to be attenuated in the natural reducing conditions in fluvial sediments adjacent to and beneath the river after the remedial action is complete."* Again, PG&E should acknowledge that the 32µg/L chromium value is a regional value. Chromium concentrations in the freshwater injection areas decrease to non-detects with depth. Therefore, any chromium introduced into the lower portions of the aquifer is providing an additional flux of hexavalent chromium above baseline conditions. Again, PG&E needs to site language from the 2009 background study report acknowledging limitations with the regional values (i.e., depth).	As stated in the technical memorandum, monitoring for arsenic will be performed during remedy implementation to verify the fate and transport modeling results, and appropriate adjustments will be made to remedy operations as needed. The Topock groundwater background study commenced in 2004 with an approved work plan and ended in 2009. This step-wise (Steps 1 through 4), multi-year study was conducted with interaction and approvals from DTSC (early years), and DTSC/DOI (later years) at every step. In January 2008, at the direction of DTSC, PG&E presented discussions of the following three topics (see attached cover letter to the January 2008 revised background study report): • Future Uses of the Groundwater Background Study Results • Potential Limitations for Use of the Groundwater Background Study • Rationale for a Single (rather than Multiple) Background Concentrations for the Topock Groundwater Study In this 2008 letter, PG&E presented the basis for its belief that the groundwater background study is not overly conservative, and may actually underestimate the natural range in background values due to the number of upper end data points eliminated during Step 2 and Step 3. As required by DTSC in the November 30, 2007 letter, a total of 30 analyses were deleted from the background study data set (including arsenic data from three background study wells in Arizona). This deletion of 30 data points has resulted in changes in the UTLs for lead and arsenic. Furthermore, PG&E presented the case that having multiple (rather than a single) background concentrations at the Topock site would result in significant scientific uncertainty, is not practical from a regulatory standpoint, and would hinder rather than advance the progress toward selection and implementation of a final groundwater remedy.



DTSC Comments and PG&E Responses

Comment Number	Comment Location (Section/Paragraph/ Page)	DTSC Comment	PG&E Response
7	2.2.2 Protection of Aquifer Water Quality, Emerging Contaminants, Page 5	The section states, "*Examples of this include the Tucson Airport Area Superfund site, where it was discovered in 2002 that 1,4-dioxane had been passing undetected through the air strippers since 1987 and was injected into a previously uncontaminated portion of the aquifer. A similar problem occurred at the Aerojet site in Rancho Cordova, CA, where perchlorate passed undetected through air strippers and was injected into a clean portion of an aquifer*." The examples cited are isolated incidences and are not the norm. It is unlikely that significant concentrations of emerging chemicals would be detected within the Topock site area due to the absence of known source areas upstream and dilution effects. Issues associated with emerging contaminants must be supported with site specific data. While emergent contaminants have been detected away from the Topock site, DTSC is unaware of any detections of perchlorate or 1,4-dioxane in any Topock site river or water well samples. PG&E tested for perchlorate as part of the interim measures activities to ensure that the contaminant would not be injected into the uplands area. DTSC assumes similar testing precautions would be taken for river water. River water could be periodically monitored for large suites of constituents. Discussion of hypothetical emergent contaminant scenarios in the future will need to be supported with site specific data or at least data in the vicinity of the site. Absent of site specific data, emergent contaminants do not appear to be a significant disadvantage to the use of river water. Please note that emerging contaminants are issues only if they exceed regulatory water quality standards. Regulatory criteria for emergent contaminants may take decades to develop and will allow for reasonable assessment and planning in the future. The section states, *"Some of these emerging contaminant compounds are not mobile in the subsurface and may never move far from the river."* If they are not mobile in the subsurface, it would seem they would also not travel much after injection.	Fortunately, examples of emerging contaminants being present in injection wells have been rare, but the consequences are severe, resulting in contamination of large areas of previously pristine groundwater. Thus, while the risk of injecting an unrecognized trace contaminant may be low, the consequences are high. The following quote is excerpted from the website of the Colorado River Regional Sewer Coalition (CRRSCo), a non-profit corporation of Arizona, California and Nevada river communities, local governments, Indian tribes, and regional water providers in the Lower Colorado River Basin. It highlights the several risks to water quality in the Colorado River, including risks from emerging contaminants: *"In April 2004, however, the environmental organization American Rivers and its partners designated the Colorado River as the nation's "most endangered river," citing mounting problems with radioactive, human and toxic waste that are contaminating groundwater levels to unsafe conditions. The situation has been compounded by rapid population growth, with the result being that areas already being served by outdated wastewater technology and septic tanks that can no longer function to treat wastewater without creating further contamination problems.* *Contamination increasingly threatens the livelihoods of those millions of Americans living in the Lower Basin states. It threatens their health. It threatens their lives. But people living in the Lower Basin are not alone in facing this water crisis. If the spread of contamination is not addressed sooner, rather than later, not only the quality of water in the Lower Basin but the quantity of water along the entire river will be in jeopardy.* *Three sources of pollution are at the heart of the contamination crisis confronting both the upper and lower basins: nitrates, uranium and chromium. In addition, there are a number of emerging pollution and biological issues further contributing to the problem, such as pesticide residues, pharmaceuticals, industrial contaminants and other endocrine disrupting compounds, salinity and quagga mussels."* DTSC is correct that regulatory standards for emerging contaminants may take decades to develop. That is precisely the concern that PG&E has. If presently unregulated contaminants are injected into the aquifer and regulations are later put in place, PG&E could be held responsible for cleanup of a newly regulated contaminant over an area much larger than the original chromium plume.

DTSC Comments and PG&E Responses

Comment Number	Comment Location (Section/Paragraph/ Page)	DTSC Comment	PG&E Response
8	3.1 Evaluation Criterion #1 -- Influence of Freshwater Pumping on Remedy Performance, Page 6	Model simulations are based on using a 600 gpm freshwater pumping rate. Would the simulations change if the pumping rate increases to the maximum of 1200 gpm as stated by PG&E? The 60% Design should also evaluate by modeling the potential issues associated with pumping at 1200 gpm as pumping may range up to this threshold.	The maximum freshwater pumping rate in the 60% design is 1,010 gpm (900 gpm for the groundwater remedy injections plus 110 gpm for TCS operations), which corresponds to injecting a maximum combined rate of 1,200 gpm into the Inner Recirculation Loop/Freshwater injection wells (900 gpm freshwater plus 300 gpm from the River Bank extraction wells). Additional model runs to examine this condition were not completed for the 60% design but are expected to show further nominal reductions in the remedial timeframe.
9	3.1.1 Conclusion, Page 7	The section states, *"Based on the solute transport model simulations, there are negligible differences between the three freshwater sources from a hydraulic perspective."* Would the conclusion be different if injection rate is ramped up to 1200 gpm?	See responses to DTSC Comment #9 as it relates to the maximum freshwater injection rate condition for the 60% design. No, within the area of concern the hydraulics are similar under elevated freshwater injection rates for the three potential freshwater sources.
10	3.2.1 Well or Wells in Arizona, Topock-2 and Topock-3 Wells, Page 7	Please provide any and all information regarding old wells Topock 1 and 2 in the 60% Design. PG&E must have information on these wells as they supplied the compressor station for years. Identify these wells on Figure 3-1 or equivalent. Indicate what maintenance/rehabbing was done to all Topock wells. The history of these older wells may help in understanding the potential future behavior of well HNWR-1. The geology/log of Topock 2 and 3 (1 & the "old" 2 also) is missing. Please provide and discuss. Topock 3 is stated to produce "poor quality water". Please elaborate on what poor quality water is. Include analytical data of poor water quality. Indicate current and historical pumping rates at all Topock wells.	PG&E purchased water from the owners of the Topock 2 and 3 wells but had no involvement in the operation of maintenance of the wells. PG&E therefore has no data on historical maintenance activities or pumping rates from these wells. The ADEQ Arizona Groundwater Study reports that the Topock 2 and 3 wells pump about 74 acre feet per year. Logs of Topock 2 and 3 are provided in Appendix B2 of the RFI/RI Volume 2 Report (CH2M HILL 2009a) but will also be included herein as requested, at the end of this RTC table. PG&E is not aware of any log for the original (old) Topock 2 well. This well was reportedly drilled in 1959 and abandoned in 1974. PG&E did locate some laboratory reports of samples from the Topock 3 well in 1978 and 1979. This is believed to be prior to the plugging of the bottom 100 feet of this well. These reports (attached at the end of this RTC table) show sodium and TDS at concentrations above recommended drinking water standards. PG&E also located some information on the former Topock 1 well, which is also attached. The data show that this well was about 34 feet deep but there is no well log. There are laboratory results of water samples from 1957, 1968, and 1980.

DTSC Comments and PG&E Responses

11	3.2.1 Well or Wells in Arizona, Conclusion for Arizona Groundwater Option, Page 9	The section should discuss the geology and hydrology of the area – detailed preferably. Knowing the geologic units in the area might help to locate areas with higher yields. Ancestral Colorado River deposits might contain more sands and gravels. Please provide a basic hydrogeologic description of the area before making hydrogeologic conclusions. Place the requested information in the 60% Design.	Unfortunately, there is no good information on the geologic units in this area. The driller's logs from existing wells are sparse and inconsistent in their descriptions. The only existing well that is installed in the Sacramento wash bottom in the vicinity of the Project Area is the HNWR-1 well. The log for this well was provided on page 7 of the Freshwater Tech Memo. This clean sand and gravel material between 83' and 156.5' is likely the desired Holocene sand and gravel that is the target for the new production well. The next nearest wells are the Topock 2 and 3 wells. These wells are located outside the channel of Sacramento Wash, so they would not have penetrated the desired Holocene gravels. The driller's log of Topock 3, the more detailed of the two logs, is provided below:  0-11 sand & boulders 11-23 gravel.sand & boulders 23-30 gravel w/ few boulders 30-33 boulder 33-43 clay 43-46 silty sand 46-52 boulders & gravel 52-91 clay w/ interbedded rock 91-146 boulders & gravel 146-180 decomposed granite 180-250 decomposed granite w/ rhyolite boulders After completion, Topock 3 well produced poor quality water. It was cemented back to a depth of 150 feet and the water quality improved. The present Topock 3 well is screened from 85 to 130 feet. It is unlikely that any of the units encountered in Topock 3 correlate with those in HNWR-1. The next nearest wells are at the Kinder Morgan compressor station and at the ADOT yard, but these wells produce water from the older alluvial fan deposits and/or bedrock, so they are not considered relevant to the target geologic units for new production wells. The next nearest well that is located near the river and might considered relevant is the RPGS (aka GSRV-2) well, located about 1.6 miles north of HNWR-1. The driller's log of the RPGS Well contains very little detail. It notes sand down to 18 feet, clay from 18 to 25 feet, and a mixture of sand and gravel down to 245 feet. Large gravel was noted between 120 and 124 feet. No bedrock was encountered. The well is not located in the bottom of a large wash where Quaternary gravels would be expected to be found, so it is likely the gravel encountered in RPGS are older than we are targeting with the new wells. About one-half mile further north from RPGS is the Serrano Landscaping well. The drillers log for this well also contains very little

DTSC Comments and PG&E Responses

Comment Number	Comment Location (Section/Paragraph/ Page)	DTSC Comment	PG&E Response
			detail. It indicates a mixture of sand, sand and gravel, and some gravelly sand to a depth of 260 feet. Boulders are noted in the uppermost 25 feet. In summary, the data from existing wells is not adequate to define any specific hydrogeologic in this area. It is encouraging that, with the exception of Topock 3, sediments encountered in all of the wells drilled along the river on the Arizona side were predominantly sand and gravel. In general, the sediments along the Arizona shore appear to be coarser grained than those typically encountered on the California side of the river.
12	3.3.1 Well or Wells in Arizona, Arsenic, Page 12	It is clear that arsenic in Arizona is elevated above the MCL of 10. Nevertheless, the receiving body of water in California is below the MCL and the proposed action will cross state jurisdiction. Currently, California Regional Water Quality Control Board is requiring PG&E to conduct additional study and possible WDR for the proposed injection.	Comment noted. As previously mentioned, the RWQCB, subject to its invitation for PG&E to seek review by the State Water Resources Control Board, indicated that the HNWR-1 water would likely need treatment to remove naturally occurring arsenic prior to injection. With the RWQCB's consent, PG&E has opened discussions with the SWRCB regarding the need to treat naturally occurring arsenic. As the SWRCB has not yet made a decision on this matter, PG&E continued to evaluate options for freshwater supply by seeking location(s) for new well(s) that could supply an adequate quantity of water of sufficient quality to not require treatment prior to use for remedy operation, and on November 20, 2012, submitted an Implementation Plan for Alternative Fresh Water Sources Evaluation (Implementation Plan) (CH2M HILL 2012g). Comments from Tribes, Agencies, and Stakeholders were received, and a Revised Implementation Plan was submitted on January 28, 2013 (CH2M HILL 2013a). The Revised Implementation Plan is currently under review by DTSC and DOI. As directed by DTSC on December 31, 2012, PG&E included a pre-injection treatment system in this 60% design. The decision by the SWRCB is anticipated to guide further direction from DTSC regarding the ultimate use of the fresh water source and what level of treatment if any will be required for various constituents. The freshwater source details will be included in an addendum to this 60% design, after such requirements are determined and completion of planned source water studies.

DTSC Comments and PG&E Responses

Comment Number	Comment Location (Section/Paragraph/ Page)	DTSC Comment	PG&E Response
13	3.3.1 Well or Wells in Arizona, Arsenic, Page 12	The section states, "*The most likely explanation is that iron oxide minerals, effective adsorbers of arsenic, are undoubtedly present in the aquifer matrix in Arizona, however, long-term exposure to the groundwater with naturally occurring arsenic has saturated all the adsorption sites on these minerals. There are a finite number of adsorption sites for matrix minerals, and if the groundwater has excess concentration of an adsorbing constituent (such as arsenic), then the matrix minerals and groundwater will form an equilibrium state, with the adsorption sites at capacity (Schindler 1991, Stumm 1992).*" If this is true, shouldn't PG&E conduct a bench test to determine the capacity of the adsorption sites to test this theory in California? If the continued loading of arsenic can potentially overwhelm the localized adsorption site causing equilibrium to be formed with arsenic, this can be a significant data gap. Wouldn't PG&E test this theory prior to actually injecting a known toxin into a beneficial aquifer? DTSC believes it to be PG&E's responsibility to ensure the protection of the State's water in every way possible.	The concentration of amorphous iron oxide that provides adsorption sites has been measured in core samples during the Aerobic Core testing study (CH2M HILL 2005a, see response to Comment 8 above). Amorphous iron oxides have been studied for their adsorption capacities and adsorption site densities (i.e. number of adsorption sites per unit mass of oxide) have been published and used in the current site model (Dzombak and Morel 1990). The combination of the measured site data and the published adsorption site densities provides a reasonable model of fate and transport of arsenic at the site. Additional sample collection and testing would add time and scope to the project. PG&E believes that groundwater monitoring would be a more effective evaluation of the modeled fate and transport. As directed by DTSC on December 31, 2012, PG&E included a pre-injection treatment system in this 60% design. The decision by the SWRCB is anticipated to guide further direction from DTSC regarding the ultimate use of the fresh water source and what level of treatment if any will be required for various constituents. The freshwater source details will be included in an addendum to this 60% design, after such requirements are determined and completion of planned source water studies.
14	3.3.1 Well or Wells in Arizona, Arsenic, Page 13	Although we do not anticipate a drastic change in geochemistry at the injection sites, what could cause desorption of the arsenic from the iron oxide in the aquifer? Would well rehabilitation measures adversely impact arsenic concentrations around injection sites?	Desorption of arsenic would require a drastic change in water chemistry surrounding the aquifer matrix. This would be in the form of a large concentration of an ion that is geochemically similar to the adsorbed arsenate, such as phosphate. Positively-charged metal ions would not have an effect, since arsenate is negatively charged, nor would anions with different properties such as sulfate and bicarbonate. Well rehabilitation rinses would only effect several feet around the well, and these fluids are not likely to contain ions that would cause significant desorption. Also, the rinses are pumped back out of the well, limiting if not eliminating their effect on the aquifer matrix near the well.

DTSC Comments and PG&E Responses

Comment Number	Comment Location (Section/Paragraph/ Page)	DTSC Comment	PG&E Response
15	3.3.1 Evaluation of water from areas with lower arsenic outside the influence of hydrothermal activities, Page 13	It is stated that "*If it becomes necessary to develop a water supply from a well in Arizona other than HNWR-1, it would likely be from a well outside the APE to the north. There are two wells north of HNWR-1 for which some information exists. Well GSRV-2 is located along Highway 95 just south of Warm Springs Wash, approximately 1.6 miles north of HNWR-1.*" Although the concentration of arsenic is below MCL at GSRV-2 area, the higher than established regional background concentration for hexavalent chromium is a concern. That Cr6 may confound the clean-up effort of the anthropogenic contamination of the same chemical. This is also not desirable for the Topock remediation.	The average Cr(VI) concentration in GSRV-2 during the background study was 25 µg/L, which is higher than in HNWR-1 but below the regional background of 32 µg/L. PG&E is proposing a contingency well much closer to HNWR-1 than to GSRV-2, where Cr(VI) is anticipated to be lower than GSRV-2 . In fact, the proposed contingency well location in this 60% design is in the vicinity of the proposed Site B in the Revised Implementation Plan for Alternative Fresh Water Sources Evaluation Tech Memo (CH2M HILL 2013a). If allowed to proceed with the Implementation Plan, water quality data will be collected at Site B.
16	3.3.1 Total Dissolved Solids (TDS), Page 14	This section discusses modeling to *"assess whether the volume of this mass would block a significant portion of the aquifer porosity. The simulation showed that less than one percent of the available porosity was blocked by re-precipitation."* However, the Tech Memo never evaluated the current IM-3 injection wells or discusses what the root causes were for the degradation of injection efficiencies at existing injection wells. Since IM-3 injection wells have been in operation for approximately six years, and well rehabilitations have taken place, the experience from those wells may be more beneficial than model simulations.	The desired concentration of manganese (<10 µg/L) specified in the tech memo is based directly on experience operating the IM-3 injection wells. When manganese concentrations are greater than 10 µg/L, plugging of the IM-3 injection wells occurs much more rapidly. Because manganese is the only constituent known to be associated with plugging at the IM-3 wells, there is no data from the IM-3 operations to evaluate plugging potential from iron or arsenic.

DTSC Comments and PG&E Responses

Comment Number	Comment Location (Section/Paragraph/ Page)	DTSC Comment	PG&E Response
17	3.3.1 Total Dissolved Solids (TDS), Page 14	This section states "*There are no wells between HNWR-1 and the marsh, so the groundwater quality in this area is unknown. Similarly, it is not known how far below the bottom of HNWR-1 the high TDS water lies. It is therefore not possible to predict what changes might occur in water quality at HNWR-1 over time with any degree of certainty. It is likely that the TDS will increase as more river water is pulled in.*" PG&E regards potential water quality issues of the Colorado River, including emerging chemicals, as a major disadvantage of using that water. Contrarily, PG&E anticipates the water quality of HNWR-1 to decrease over time, but PG&E has not identified any potential testing or further evaluation of the water in that area for sustainability. Shouldn't PG&E evaluate or test the current water quality at the marsh as an indicator of possible outcome prior to selection of HNWR-1 as the preferred option? DTSC expects this level of evaluation to support the design.	The water in the marsh comes from the river and there are no sources of emerging contaminants or other pollutants in the Topock Marsh. The primary factor that would cause a difference in water quality between the marsh and the river is evaporative concentration of minerals in the marsh. In his Ph.D. dissertation, Bradley Guay estimates about 46% of the water entering the marsh is lost to evaporation. The data show a 5- to 6-fold increase in specific conductance between the marsh inlet and the downstream sampling point which was somewhere above the south dike. HNWR-1 is located in a portion of the marsh below the south dike. There is an exchange of water in this section of the marsh as the river level fluctuates. The TDS is likely somewhat lower in this part of the marsh due to dilution with river water. There are likely seasonal changes in water quality associated with differences in evaporation rate and river levels. Establishing baseline water quality in the marsh near HNWR-1 would likely require multiple sampling events at different times of the day and different seasons. However, even if the water quality in the marsh is known, there is no way to accurately predict how this would affect the water quality in HNWR-1 because one does not know how much river water will be drawn in and what the character of that water will be after it passes through the reducing rind and reaches HNWR-1. There are adequate data available from the MWD database to assess the quality of water in the river. There is no reason to suspect any exotic contaminants would be introduced as water flows through the marsh. It can therefore be assumed that the concentrations of whatever is in the river would be increased by about a factor of 5 or 6 in the marsh. Not all the constituents present in river water would be mobile in groundwater. For those constituents that are mobile, there would be considerable attenuation through dilution and dispersion prior to reaching HNWR-1. Therefore, obtaining water from HNWR-1 provides a significant buffer against inadvertent injection of anything harmful that might be present in river water. Unfortunately, without detailed hydrogeologic studies involving installation of multiple monitor wells and long term pumping tests at HNWR-1, it is not possible to predict how the water quality in the marsh may affect the water quality in HNWR-1 over the decades long operational period of the remedial action.

DTSC Comments and PG&E Responses

Comment Number	Comment Location (Section/Paragraph/ Page)	DTSC Comment	PG&E Response
18	3.3.1 Conclusion for Arizona Groundwater Option, Page 15	PG&E concluded that treatment of arsenic is not needed. However, as stated in prior comments, this conclusion may not be supported by California agencies and may not meet ARAR for the California Water Resources Control Board's resolution 68-16. PG&E is currently evaluating this issue.	Comment noted.
19	3.3.1 Blending with water sources with lower arsenic, Page 16	PG&E has neglected, in this tech memo, to evaluate the possibility of blending water from Park Moabi area with existing Topock 2 and 3 water. PG&E is currently acquiring water from Topock 2 and 3 for compressor station use, therefore no additional infrastructure is needed. Importing additional water from Topock 2 and 3 seems possible based on combined yield. By installing only well(s) from Park Moabi for blending, the additional infrastructure would be minimal while possibly meeting the water quality and quantities needed for the remedy.	As described in the Freshwater Source Evaluation tech memo, a careful review of the available data indicates that a well producing from the high quality water zone at Park Moabi would produce less than 100 gpm and the pumping would likely produce adverse impacts on existing Park Moabi wells. The Topock 2 well could likely produce about 400 gpm, but there is a risk of upconing of more saline water from depth. In addition, the arsenic concentration of Topock 2 is similar to that of HNWR-1 (about 15 µg/L). In order to have arsenic below the MCL of 10 µg/L, assuming that the new Park Moabi well contained no arsenic, it would be necessary to blend water at a ratio of approximately 1/3 from Park Moabi and 2/3 from Topock 2. With the maximum modeled fresh water flow rate of 900 gpm, the new well at Park Moabi would need to produce about 300 gpm. If it contained any arsenic, the amount of water needed from Park Moabi would be even greater. Based on the available data, PG&E does not believe that a well at Park Moabi would provide a sufficient volume of water to blend with Topock 2/3 water and result in an arsenic concentration below the MCL. The existing pipeline from Topock 2/3 would also need to be replaced or a second pipeline installed in order to accommodate the balance of the maximum modeled flow rate. In addition, another well in Arizona would need to be installed to ensure adequate quantity from Arizona, and this well would need to somewhere far enough from Topock 2/3 to avoid interference. Therefore, the amount of infrastructure needed to blend water from two sources could be greater than for the HNWR-1 well alone because it would require new piping to be installed from both Park Moabi and from Arizona and a new well in Arizona. In PG&E's opinion, the concept of blending water from Park Moabi and Topock 2/3 does not appear to offer any advantages over obtaining water from HNWR-1.

DTSC Comments and PG&E Responses

Comment Number	Comment Location (Section/Paragraph/ Page)	DTSC Comment	PG&E Response
20	3.3.3 Colorado River, Total Dissolved Solids, Page 22	The average TDS of the river is stated, but the source of the data set in not identified. DTSC assumes that the TDS exhibited by the river, while ranging, would exhibit consistent values over the years that it has been monitored, and, therefore, would be consistent over the life of the remedy. This would be in contrast to HNWR-1 where the TDS values from the well as it is pumped continuously over the life of the remedy could change significantly. Projecting TDS variability during the life of the remedy for both the river and HNWR-1 should be evaluated and addressed in the 60% Design. This is important as low TDS is a major desirable quality of the HNWR-1 source.	The TDS data are from the PG&E river monitoring program. As noted previously, there are no data to support a projection of the possible trends in water quality in HNWR-1 over the life of the remedy. Neither are there data to support a projection of TDS in the river. This is stated in Section 3.3.2 of the 60% design.
21	3.3.3 Colorado River, Coliform Bacteria, Page 22 & 23	The section cites coliform bacteria levels measured from Lake Havasu located at least 15 miles downstream of Topock and Whitsett Intake located at least 35 miles downstream. Citing data so far away and near a major city seems inappropriate for this evaluation and casts doubt on the utility of the data and statements in the section. Is this an issue at the Topock area?	There are no data on coliform bacteria in the river at Topock, however it should be noted that Topock is downstream from Needles and Laughlin so there is the potential for bacterial contamination to be present at Topock due to discharges from septic systems or sewage treatment plants.
22	3.3.3 Colorado River, Perchlorate and Nitrate, Page 23	The section states that perchlorate was not analyzed in samples collected near the Topock site. This is an incorrect statement. PG&E should review its data set and note the couple of perchlorate nondetects from locations CON and I-3 in 2003. Mention of the perchlorate analyses in groundwater (all nondetects), especially in wells located adjacent to the river, should also be mentioned.	DTSC is correct. There are two perchlorate sample results in the PG&E river monitoring database, both non-detect with a detection limit of 4 ppb. Prior to the IM-3 pumping there was a net discharge of groundwater in the floodplain to the river. Therefore, perchlorate might not be detected in wells near the river even if it were present in the river.
23	3.3.3 Colorado River, Contaminants with Secondary MCLs, Page 23	The section notes a maximum elevated aluminum concentration of 540 µg/L in river water. As this value appears anomalous compared to the other data, PG&E should evaluate why it might be elevated. Are the data presented in Tables 3-7 and 3-8 samples that were filtered or unfiltered or a mixture of both?	According to MWD, the only filtered water is the water for Cr(VI) analysis.
24	3.3.3 Coliform Bacteria, Page 23	What are the physical methods that can be used to remove biological growth from well screens? If disinfection is required, will the disinfectant process also adversely impact microbes necessarily to establish the reduction zone?	Biological fouling doesn't generally respond well to strictly physical methods of removal. In IRZ wells, citric acid is sometimes used to help break down slime forming microbial growth prior to surging and bailing or pumping. Disinfectants are not typically used in IRZ well rehab because of the potential for damage to the microbial community needed to maintain reducing conditions. Disinfectants could be used in freshwater injection wells where there is no need to maintain a microbial community.

DTSC Comments and PG&E Responses

Comment Number	Comment Location (Section/Paragraph/ Page)	DTSC Comment	PG&E Response
25	3.3.3 Compounds Associated with Pharmaceuticals and Personal Care Products, Page 23	PG&E concludes that "*As areas become more or less populated over the next few decades, it is expected that the presence of PPCP compounds in river water to vary accordingly. In addition, as new and more advanced/exotic personal care products and pharmaceuticals are brought to the market as society advances over the next few decades, it is likely that new trace contaminants could be found in river water.*" While this may be true, this same argument can be applied to additional population that could impact the quality of water from the Sacramento wash on which the HNWR-1 depends.	The potential for significant population increases in existing communities along the Colorado River seems much greater than for sparsely inhabited and somewhat austere Sacramento Valley.
26	3.3.3 Colorado River, Compounds Associated with Pharmaceuticals and Personal Care Products (PPCP)/Emerging Contaminants, Page 23 & 24	PG&E's concerns with PPCP and emerging contaminants appears speculative at this point as a data gap exists regarding river water quality in the immediate vicinity of the site. The site is located away from more populated areas where these contaminants are stated to be more of a concern. There may simply be no problem with the river water in the Topock area. Data should be collected at the site to determine if there is any concern. Continued monitoring during the remedy would ensure that river water quality was always acceptable. The section states, "*Some of these emerging contaminant compounds are not mobile in the subsurface and may never move far from the river. If fresh water were obtained from a well rather than from the river, this travel time from the river to a well provides a buffer that might allow for mitigation measures to be implemented prior to injecting an emerging contaminant and having it spread across the site.*" This is not a concern as monitoring would always be conducted to provide a warning system against undesirable constituents. Non-mobile constituents would also not move far in groundwater away from an injection well.	See response to DTSC comment 7. Concentrations in the river could change rapidly due to upsets in sewage treatment plants or rainfall events. Monitoring for compounds for which there are currently no standards would not prevent injecting them at concentrations above a future standard. The safest course is to not inject raw river water, but rather seek a groundwater supply which is buffered from the potential short term fluctuations in concentrations in the river and not likely to become contaminated with river water for many years.
27	3.3.3 Potential Need for Conditioning of River Water Prior to Injection, Page 24	PG&E states that it plans to screen extraction wells in the lower, oxic portion of the aquifer. Please note, however, that many stakeholders are expecting these extractors to be a stop gap for any contaminants which may flow into the river. The current design will not meet that expectation and PG&E must consider a separate contingency plan for capturing contaminants that may move toward the river.	The 60% design document discusses possible contingency measures for the river bank wells. If it becomes necessary to pump from the reduce zone in the shallow aquifer, treatment will likely be required to remove iron and manganese prior to injection.

DTSC Comments and PG&E Responses

Comment Number	Comment Location (Section/Paragraph/ Page)	DTSC Comment	PG&E Response
28	3.3.3 Colorado River, Potential Need for Conditioning of River Water Prior to Injection, Page 24	• The section states that solids and bacteria/microorganisms will need to be removed prior to injection. The level at which conditioning is required should be stated. What concentrations of solids and bacteria/microorganisms are considered undesirable and would require conditioning? • Shallow infiltration galley: It is uncertain what different type of intake structures can be designed. The Tech Memo/30% should have discussed the range of alternatives. Can an intake screen be placed on the bottom of the river and then covered with permeable materials and armor to allow freshwater infiltration? • The section discusses PGE-8 and PGE-9 without discussing where these wells are located. DTSC believes they are misnamed and referring to wells PGE-9N and PGE-9S located on the Arizona shore under the arch bridge.	• Ideally, suspended solids and bacteria should be less than 2 mg/L. Less is better as any amount contributes to plugging and over the 50 year life of the remedy, even a small amount could significantly reduce the live of the injection wells. • Park Moabi attempted a shallow infiltration gallery and it produced very poor quality water. The pore water samples showed reduced conditions in all but one of 64 locations at shallow depths (~6feet) below the river bottom. If an intake were installed in the geochemically reduced bottom sediments, a treatment plant would likely be needed, at least initially, to remove iron and manganese prior to injection. • DTSC is correct, the memo should refer to PG&E 9N and 9S.
29	3.3.3 Potential Need for Conditioning of River Water Prior to Injection, Page 26	PG&E estimated the conditioning facility to be 5,400 square feet. It is unclear how this estimate was developed. With the exception of the disinfection tank, the treatment system process appears very similar to the pre-treatment system for arsenic. What is changed so that the treatment system would be more than doubling the size?	The disinfection function and the phase separators (similar to IM-3) were the primary differences between the River Water Conditioning Facility and the arsenic treatment system. In addition, Additional space was allocated to incorporate elements such as electrical transformers, and other items needed to integrate this facility with the Remedy and TCS operations.
30	3.4.1 Initial Design, Page 28	DTSC understands that there are numerous intake and fish screen designs, why did PG&E selected the round pipe with circular continuously cleaning design as the preliminary choice? Non-continuously cleaning or flat screens?	The round, continuously cleaning (ISI) screen is a proven design in small-flow, river applications similar to Topock. The screen can be removed from the water for easy inspection and maintenance.
31	3.4.1 Initial Design, Page 29	PG&E states "*Preliminary discussion with CDFG indicated that approval of a fish screen and intake structure that would avoid incidental take of the razorback sucker may be difficult to obtain.*" Perhaps this is a good discussion to invite Fish and Game for CWG meeting to provide understanding and hurdles involved.	Comment noted.
32	3.4.1 Initial Design, Page 29	When will the fish habitat assessment report be available? Since that would dictate, in part, the viability of an intake structure.	The Instream Habitat Typing Survey Technical Memorandum was submitted to DTSC on May 25, 2012, and is included in Appendix A6 of this 60% BOD.
33	3.4.1 Initial Design, Page 29	Where are the representative visuals for Sites 1 and 2? Are they similar to Site 3? There is limited explanation for the photo provided.	The visuals for Sites 1 and 2 are included in the *Instream Habitat Typing Survey Technical Memorandum* (CH2M HILL 2012f). This memorandum was submitted to DTSC on May 25, 2012, and is included in Appendix A6 of this 60% BOD.

DTSC Comments and PG&E Responses

Comment Number	Comment Location (Section/Paragraph/ Page)	DTSC Comment	PG&E Response
34	3.4.1 Initial Design, Page 30	PG&E states that "Based on the preliminary engineering evaluation and fish habitat survey, Site 4 appears to be the most feasible location for a river intake structure and fish screen…" However, there is no supporting discussion on the criteria used for this determination or the rationale for this statement. More importantly, Site 4 is also the closest location to the visible manifestation of the maze. This area also has more recreational users and boaters traveling through the area. A more thorough evaluation and discussion should have been prepared.	Section 3.4.1 (Initial Design) of the Freshwater Source Evaluation Tech Memo is intended to present a summary of the preliminary engineering survey and initial design. Attachment B of the Tech Memo includes additional details and evaluation including a comparison table of the sites evaluated against the evaluation criteria that support the conclusion.
35	4.0 Selection of Preferred Freshwater Source, Page 39	PG&E concludes that the HNWR-1 well in Arizona is the preferred freshwater supply option for the remedial action because it *"…presents less uncertainty, less risk to project schedule, and less disturbance of the site."* PG&E may be correct in selecting HNWR-1 as the preferred option; however, based on the comments above, DTSC believes that there are still significant uncertainties associated with its use. Specifically, the arsenic above MCL and above the concentration of the receiving water body may be problematic. If pretreatment of the arsenic is necessary prior to injection, site disturbance would be significant as a water treatment plant and significant length of pipeline would be needed for this option. Furthermore, PG&E has not evaluated the long term water quality at HNWR-1. What would be PG&E's response if TDS increases sharply from sustained extraction?	Exhibit 3-11 of Freshwater Source Evaluation Tech Memo presents a contingency matrix for some of the more serious types of problems that might be associated with the freshwater sources or with the injection of fresh water at the Topock site. One of the contingencies described in the matrix is pumping that draws in saline water from below or geochemically reduced water from the river or the marsh. The possible contingency measures listed for this contingency include install treatment to remove harmful constituents or seek other source(s) of fresh water or other location for well(s). As directed by DTSC on December 31, 2012, PG&E included a pre-injection treatment system in this 60% design. The decision by the SWRCB is anticipated to guide further direction from DTSC regarding the ultimate use of the freshwater source and what level of treatment if any will be required for various constituents. The freshwater source details will be included in an addendum to this 60% design, after such requirements are determined and completion of planned source water studies.

California Department of Toxic Substances Control
5796 Corporate Avenue
Cypress, CA 90630

Subject: Revised Groundwater Background Study, Steps 3 and 4: Report of Results PG&E Topock Compressor Station, Needles, California

Dear Mr. Yue:

This letter transmits the *Revised Groundwater Background Study Step 3 and 4: Report of Results* for the Pacific Gas and Electric Company (PG&E) Topock Compressor Station site. This report incorporates changes to the *Groundwater Background Study Steps 3 and 4 Results* report dated January 26, 2007, in response to the California Department of Toxic Substances Control (DTSC's) letter dated November 30, 2007, and the U.S Department of Interior's (DOI's) letter dated December 20, 2007. As agreed with DTSC and DOI, this revised report does not address two comments:

1. The outlier evaluations documented in this *Revised Groundwater Background Study Step 3 and 4: Report of Results* were performed using the mean concentrations for each analyte and well, for the reasons described in Section 2.2. DTSC has requested an additional outlier evaluation for each constituent considering all the measured concentrations for that constituent, rather than each well's mean concentration for that constituent. This additional outlier evaluation will be performed and the results will be reported separately from this report at a future date.
2. The background study wells included in this *Revised Groundwater Background Study Step 3 and 4: Report of Results* were those selected and approved through Steps 1 and 2 of the groundwater background study. DOI's letter dated December 20, 2007 indicates that the inclusion of three of the selected wells should be conditional on the results of the planned groundwater investigation in Arizona. If chromium is found above regional background levels on the Arizona side of the River, the decision to include the three wells in the vicinity of the Arizona investigation in the background study would need to be re-evaluated.

The remaining comments in DTSC's November 30, 2007 letter and DOI's December 20 letter are addressed in the *Revised Groundwater Background Study Step 3 and 4: Report of Results.* As directed by DTSC in the November 30, 2007 letter, the following three discussion topics are presented in this letter:

Topic 1 - Future Uses of the Groundwater Background Study Results

As discussed in the approved work plan[1], the objective of the background study is to define an upper threshold background concentration for total chromium, hexavalent chromium and other inorganic constituents in groundwater at the Topock site. The upper threshold concentration represents the upper concentration of the constituent in natural groundwater not affected by contamination and is referred to as a background concentration. These concentrations are reported in the form of statistical upper tolerance limits (UTLs). The UTL is an EPA-recommended, and widely accepted, statistical method for determining a background value from a set of data. The UTL represents a value that 95 percent of the population will fall below with 95 percent confidence.

The background study will be used during the Resource Conservation and Recovery Act (RCRA) and Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) processes to:

- Support the RCRA Facility Investigation/Remedial Investigation (RFI/RI) and risk assessment activities at the Topock site and to provide a basis by which the list of constituents of potential concern (COPCs) can be evaluated and, if necessary, revised. For site characterization, this would include using the background concentrations to help distinguish the nature and extent of site-related contamination vs. naturally occurring levels of inorganic constituents. For COPC evaluation, the background concentrations can be used as points of comparison so that assessment is focused on those constituents that are elevated above naturally occurring levels. For risk assessment, background concentrations can be used to help identify the site-related chemicals so that they can be evaluated in the risk assessment, and those that contribute most significantly to risk can be identified. Background concentrations can also be useful in communicating risk to the public, putting site-related risks in perspective by comparing those risks to risks associated with background conditions at the site.

- Assist with the Corrective Measures Study/Feasibility Study (CMS/FS) activities at the Topock site during the development of remedial action/corrective action goals. Consistent with the National Contingency Plan, remedial action goals are derived based on two threshold criteria: overall protection of human health and the environment, and compliance with Applicable, or Relevant and Appropriate, Requirements (ARARs). Background concentrations may be used during the risk assessment process to develop remedial goals, particularly if the risk assessment indicates that risk-based remedial goals are lower than naturally occurring background levels. Background concentrations are also cited in certain chemical-specific ARARs, such as California's groundwater and vadose zone protection standards that are applicable to RCRA hazardous waste interim status treatment, storage and disposal facilities[2].

[1] Work Plan for Assessing Background Metals Concentrations in Groundwater, PG&E Topock Compressor Station and Vicinity, Needles, California. June 2004.

[2] U.S. Department of the Interior Preliminary Determination of Applicable, or Relevant and Appropriate, Requirements for the Pacific Gas and Electric Company Topock CERCLA Site

Topic 2 - Potential Limitations for Use of the Groundwater Background Study

As has been discussed with DTSC and DOI and noted in DTSC's November 30 letter and DOI's December 20 letter, the data collected for this study may be interpreted to represent two or more populations based on geochemical or geological distinctions. During preparation of the RFI/RI, risk assessment, and CMS/FS, the use of the background groundwater concentrations determined through calculation of UTLs for the study area as a whole will be evaluated, noting that the calculated UTLs may not be appropriate for all constituents in all portions of the site or at all depths.

Examples of populations or subpopulations that could be separated out from the background data set are discussed below:

- Groundwater in fluvial material that is influenced by the Colorado River vs. groundwater in alluvial material away from the river's influence. The latter is typically geochemically oxidizing whereas the former is relatively reducing, and this difference is expressed by differences in concentrations of several chemical parameters, including nitrate, ammonia, and oxidation-reduction potential. Section 2.2 of the *Revised Groundwater Background Study Step 3 and 4: Report of Results* identifies which inorganic constituents are dominant in the fluvial and alluvial waters and which are detected at low frequency.

- Groundwater in the alluvial aquifer is stratified and shows distinct differences from shallow to deep zones. For example, shallow alluvial groundwater in the area around well MW-18 and the Interim Measure No. 3 injection field contain hexavalent chromium, Cr(VI), concentrations that are greater than concentrations found in deeper wells in the same area, coupled with relatively low dissolved solids and major ion concentrations. Although these relatively elevated Cr(VI) concentrations are naturally occurring, they may be interpreted as representing a distinct geochemical zone that is not found elsewhere. It is common to observe shallow alluvial wells in non-plume areas of the Topock Site with relatively lower dissolved solids concentrations and more oxidizing conditions than in deeper alluvial wells. Consistent with the geochemical environment of the shallow zone, Cr(VI) concentrations in shallow wells also tend to be greater than in deeper wells.

- Three background study wells located immediately across the Colorado River from the site contain relatively higher concentrations of arsenic and fluoride, and may represent another distinct geochemical environment. Slightly elevated groundwater temperature has been observed in samples from one of these wells. These observations suggest there may be localized geothermal influences in this area. At DTSC's request, arsenic concentrations from these three wells and fluoride concentrations from one of these wells were excluded from the data set.

These groupings are subject to interpretation, and are described in Section 2.2 of the *Revised Groundwater Background Study Step 3 and 4: Report of Results*.

As required by DTSC's November 30th letter, a total of 30 analyses have been removed from the background study database that had been used to calculate UTLs for the *Groundwater Background Study Steps 3 and 4 Results* report dated January 26, 2007. Using box-and-whisker and probability plots, these analyses were interpreted by DTSC as being non-representative of

the database as a whole. The deletion of these 30 analyses from the background study data set has resulted in changes in the UTLs for lead and arsenic.

Topic 3 - Rationale for a Single (rather than Multiple) Background Concentrations for the Topock Groundwater Study

The approach to and design of the groundwater background study was documented in the approved work plan and study results (Phase 1, Phase 2, Phase 3/4 results). The definition of the background groundwater study area is the unconsolidated alluvial aquifer of the Mohave Groundwater Basin stretching from the Topock site in the south to Needles in the north (approximately 15 miles north of the Topock Site) and from the edge of the alluvial aquifer along the mountain front in the west to several miles east of the site in Arizona. Over 150 wells in the study area were evaluated during Step 1 of the background study. During Step 2 of the background study, 36 wells were sampled and screened for inclusion in the final data set. Factors considered in including the final set of wells included whether the groundwater general chemistry is consistent with the southern Mohave Valley groundwater general chemistry; whether a potential anthropogenic source may affect the concentrations of metals in groundwater; and whether the well was located within a cluster of other background wells which could cause a geographic bias. And as documented in the *Revised Groundwater Background Study Step 3 and 4: Report of Results,* outlier and geochemical evaluations were performed during Step 3 to maximize the representativeness of the groundwater background study data to the Topock site. One of the defining goals of the DTSC-approved background study protocol was to consider a wide range of geologic and geochemical regimes in developing a background number that would truly be representative of the area as a whole. The Cr(VI) concentrations found in the background study are consistent with those reported in other published studies in the region.

PG&E believes that the results of the groundwater background study are appropriate for completion of the RFI/RI and CMS/FS, are not overly conservative, and may actually underestimate the natural range in background values due to the number of upper end data points eliminated during Step 2 and Step 3. Although there is scatter in the dataset, this is expected in natural geochemical environments.

The derivation of separate background concentrations for various portions of the site has been suggested by some DTSC and DOI reviewers. PG&E believes that the development of multiple background concentrations would be subject to significant scientific uncertainty in categorizing well populations (and accommodating ranges of and changes to well chemistry), is not practical from a regulatory standpoint, and would hinder rather than advance the progress toward selection and implementation of a final groundwater remedy at the site. Moreover, the dataset collected for this study based on the approved work plan is aimed at identifying one background number for the entire study area. More specifically:

- Under a multiple population approach, the dynamic nature of groundwater flowing under the influence of current or future extraction/injection remedies could result in wells being shifted from one population to the other over time – resulting in a complex and potentially conflicting regulatory framework with no commensurate benefits.
- The methodology for defining which wells are associated with which population would be arbitrary and would be difficult to apply in practice. The boundaries of the datasets

would be indistinct, with individual wells falling partly in several different populations, depending on which constituent was being considered.

- Developing multiple populations would significantly delay proceeding to the final remedy as various aspects of the approach are challenged by stakeholders and/or further background study data collection is necessary to address an issue that was not the objective of the approved Background Study workplan.

Do not hesitate to contact me at (805) 234-2257 with any questions or comments on this information or the enclosed report.

Sincerely,

Yvonne Meeks
Topock Project Manager

LEGAL DESCRIPTION: WELL SITE NO.1

A Parcel of land being situate in and parts of Lot 1, Section 2, Township 15 North, Range 21 West and Section 35, Township 16 North, Range 21 West of the Gila and Salt River Meridian, Mohave County, Arizona and being more particularly described by metes and bounds as follows;

Commencing at the 1/4 Section Corner common to said Section 2 and said Section 35, which point is marked by a 3" Aluminum Cap, set by the U.S. Fish and Wildlife Service, thence along the line common to said Section 2 and Section 35, S 89°44'18"W, 1504.30 feet to an intersection with and a point in the westerly right of way line of old U.S. Highway 66 and a point in the southerly line of herein described Parcel and the True Point Of Beginning;

Thence from said True Point Of Beginning and along the northwesterly right-of-way line of said old U.S. Highway 66, and the southeasterly line of herein described Parcel and along the arc of a true curve to the right, having a radius of 2839.93 feet and a back tangent of N 28°44'47"E, and through a central angle of 6°56'24" southwesterly 343.98 feet to a point and corner of herein described Parcel;

Thence leaving the northwesterly right-of-way line of old U.S. Highway 66, and along the southwesterly line of herein described Parcel, N 49°24'05"W, 494.99 feet to a point and corner of herein described Parcel;

Thence along the northwesterly line of herein described Parcel, N 40°35'55"E, 460.00 feet to a point and corner of herein described Parcel;

Thence along the northeasterly line of herein described Parcel, S 49°24'05"E, 416.99 feet to an intersection with and a point in the northwesterly right-of-way of said old U.S. Highway 66 and a corner of herein described Parcel;

Thence along the northwesterly right-of-way line of said old U.S. Highway 66, and the southeasterly line of herein described Parcel, and along the arc of a true curve to the right, having a radius of 2839.93 feet and a back tangent of N 26°15'45"E, and through a central angle of 2°29'02", southwesterly 123.11 feet to the True Point Of Beginning, said herein described Parcel containing 4.88 acres, more or less and is conveyed subject to any and all easements, reservations and rights-of-way of record or as may otherwise exist.

Gentlemen:

RE: Chemical Analysis for addressee

Water System No. 08-033, Collected on 5-16-80

Sample type: Source X, System _____, Unknown _____

The interpretation of the chemical examination of the attached laboratory report No. 221-0505 shows that this sample does not exceed the maximum contaminant levels for inorganic chemicals and therefore is acceptable for use in a public water system in accordance with State regulation R9-8-221. This is not an approval of the referenced public water system, but merely an evaluation of the chemical quality of a sample of water which has been taken from that system.

REQUEST FORM TO CHANGE WELL INFORMATION
OWNERSHIP * DRILLER

Please complete the appropriate section of this request form and return to the above address with applicable fee. NOTE: A.R.S. §45-593.C requires that the Department be notified of change of well ownership and that the new owner is required to keep the Department's Well Registration records current and accurate. Well data and ownership changes must be submitted within thirty days after changes take place.

SAVE THIS FORM TO REPORT FUTURE CHANGES IN OWNERSHIP, CHANGES IN ADDRESS, OR CHANGE IN WELL DATA SUCH AS PUMP CAPACITY, CORRECTION OF LEGAL DESCRIPTION, CHANGE OF WELL DRILLER AND AMENDING INFORMATION PREVIOUSLY FILED.

1. CHANGE OF WELL INFORMATION: (NO FEE REQUIRED)

NOTE: If the location of the proposed well changes after drilling authority has been issued, attach a $10.00 reissue fee for each well.

WELL REGISTRATION NO. 55- N/A FILE NO: _____

If known, I/We request the following well information be changed: _____

RECEIVED
JAN 3 1996
GROUNDWATER MGT

2. STATEMENT OF CHANGE OF WELL OWNERSHIP: ($10.00 FEE REQUIRED)

If this change consists of more than one well and the names are common: attach a $10.00 fee. Otherwise, each well requires a separate fee of $10.00.

I, The City of Needles, state that I am the Previous/~~New Owner~~ of the well described below:

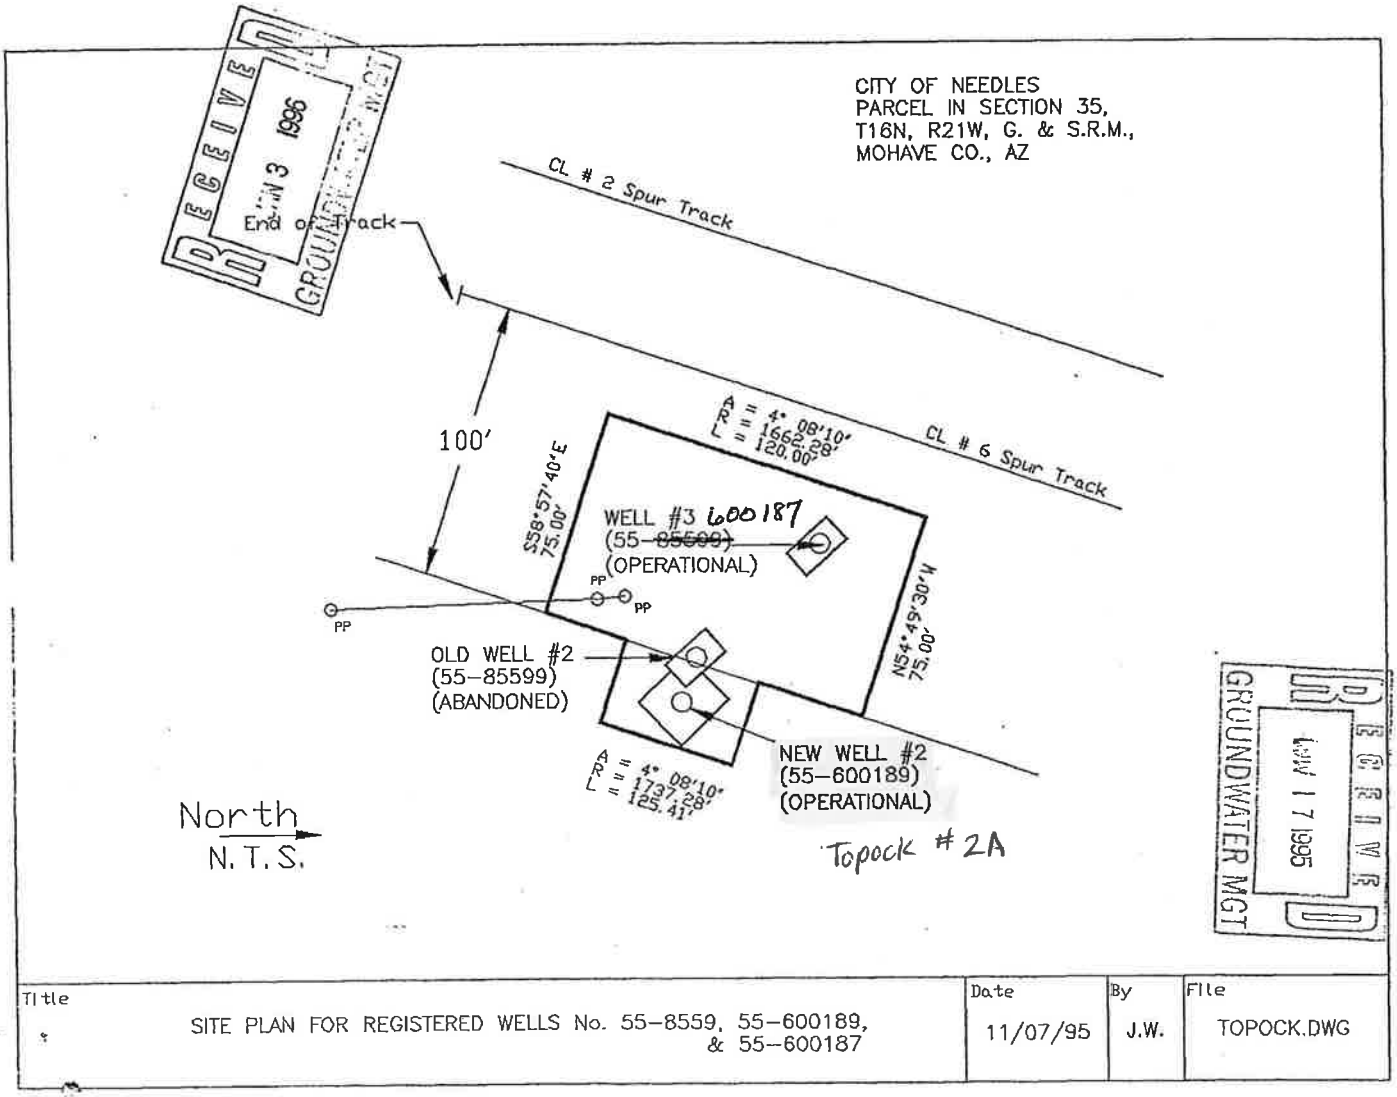
LEGAL DESCRIPTION: WELL SITE NO. 2 & 3

A Parcel of land situate in and being a part of Section 35, Township 16 North, Range 21 West of the Gila and Salt River Meridian, Mohave County, Arizona and being more particularly described as follows;

Commencing at the South one quarter (1/4) of said Section 35, thence along the southerly line of said Section 35, S 89°44'18"W, 1007.15 feet to an intersection with and a point in the easterly right-of-way line of The Atchison, Topeka and Santa Fe Railway;

Thence along the easterly right-of-way line of The Atchison, Topeka and Santa Fe Railway, N 38°39'33"E, 501.01 feet to a point of curve;

Thence along the arc of a true curve to the left having a radius of 1737.28 feet and through a central angle of 7°37'13", northeasterly an arc distance of 231.06 feet to the True Point Of Beginning and the corner of herein described Parcel;



Thence from the True Point of Beginning and corner of herein described Parcel and continuing along the easterly right-of-way line of The Atchison, Topeka and Santa Fe Railway and the arc of a true curve to the left having a radius of 1737.28 feet and through a central angle of 4°08'10", northeasterly an arc distance of 125.41 feet to a point and corner of herein described Parcel;

Thence leaving the easterly right-of-way line of The Atchison, Topeka and Santa Fe Railway and along the northeasterly line of herein described Parcel, N 54°49'30"W, 75.00 feet to a point and corner of herein described Parcel;

Thence along the northwesterly line of herein described Parcel and along the arc of a true curve to the right, having a radius of 1662.28 feet and through a central angle of 4°08'10", southwesterly an arc distance of 120.00 feet to a point and corner of herein described Parcel;

Thence along the southwesterly line of herein described Parcel, S 58°57'40"E, 75.00 feet to the True Point Of Beginning, said herein described Parcel containing 0.21 acres, more or less, and is conveyed subject to any and all easements, reservations and rights-of-way of record or as may otherwise exist.

Owner of
Well Site Southwest Gas of Arizona

File No. B(16-21)35 cdd

COMPLETION REPORT

1. Completion Report to be filed with the Department within 30 days after installation of pump equipment.

2. The tested pumping capacity of the well in gallons per minute for a non-flowing well should be determined by measuring the discharge of the pump after continuous operation for at least 4 hours and for a flowing well by measuring the natural flow at the land surface.

3. Drawdown of the water level for a non-flowing well should be measured in feet after not less than 4 hours of continuous operation and while still in operation and for a flowing well the shut-in pressure should be measured in feet above the land or in pounds per square inch at the land surface.

4. The static groundwater level should be measured in feet from the land surface immediately prior to the well capacity test.

LOCATION OF THE WELL

Topock-2

T16N, R21W, Sec. 35, SE¼ SE¼ SW¼ .

Date Well Completed 9-24-80 Depth of Well 140'

1. Well Test:
Test Pumping Capacity 400 (Gal. per min.) Date Well Tested 10/15/80

Method of Discharge Measurement Current Meter (weir, orifice, current meter, etc.)

Static Groundwater Level 50' 8" ft. Drawdown 25' ft.

Total Pumping Lift 425' ft. Drawdown _____ lbs. (Flowing Well)

2. Equipment Installed:

Kind of Pump Submersible Turbine (turbine, centrifugal, etc.)

Kind of Power Elec (Elec., Nat. Gas, Etc.) H.P. Rating of Motor 60

I HEREBY CERTIFY that the above statements are true to the best of my knowledge and belief.

Please find attached a copy of the analysis on the water sample you recently sent us. The well is most likely clogged with both hard water and calcium carbonate scale. We would recommed using our Dry Acid Special to clear up this problem.

Please also note the high chloride content and the statement that this water does not meet USPHS drinking requirements.

Very truly your,

COTEY CHEMICAL CORPORATION

Topock-2/3 Pump Test Results

(*On CD-ROM only*)

Summary of Pumping Tests at Topock 2 and 3 Wells, PG&E Topock Compressor Station, Needles, California

PREPARED FOR: Pacific Gas and Electric Company

PREPARED BY: CH2M HILL

DATE: July 25, 2012

Introduction

In support of the groundwater remedy design, pumping tests were conducted in the Topock 2 and Topock 3 wells in December 2011. The purpose of these tests was to evaluate the pumping capacity and efficiency of these wells as a potential supply of fresh water for the remedy. The wells, which are currently owned and operated by Southwest Water, provide water to three residences and the PG&E Topock Compressor Station (referred herein as "Compressor Station"). The usage by the residences averages less than one gallon per minute (gpm), assuming continuous pumping. The Compressor Station uses about 100-110 gpm. The wells feed a storage tank in Arizona that serves the residential customers and two storage tanks at the Topock Compressor Station that provide water to the Compressor Station.

Both wells are equipped with the same make and model of pump, with a maximum pumping rate of about 200 gpm. The pumps are set at a depth of about 105 feet ('). Static depth to water at the time of the test ranged between 54' and 57', allowing for a maximum of 50' of available drawdown in each well. The Topock 3 well (referred to as SWW-2 by Southwest Water) was pumped in the afternoon of December 13th, between about 2:30 and 4:10 pm. The Topock 2 well (SWW-1) was pumped in the morning of December 14th, between about 8:30 and 10:00 am.

The pump test method was a step-drawdown test, where the pumping rate was increased incrementally in a series of steps while drawdown was measured in the pumping well. This test was designed to evaluate the performance of the well rather than measure the properties of the aquifer. The test method is based on an equation developed by Jacob (1946) that describes the drawdown in the well as a sum of a first order (laminar) component (BQ) and a second order (turbulent) component (CQ^2):

$$s = BQ + CQ^2$$

Where s represents drawdown, Q represents pumping rate, and B and C are constants specific to the well and aquifer.

Biershenk (1964) developed a graphical method to solve for B and C. By plotting s/Q against Q, the data from a step test forms a straight line with slope C and intercept B.

Topock 2 (SWW-1) Test Results

The Topock 2 well was pumped in a series of four steps at rates ranging from 108 to 202 gpm (Figure 1). The maximum drawdown observed was about 5.6'. This well appears to be fairly efficient. The driller's report from 1980 notes a drawdown of 25' at a pumping rate of 400 gpm, corresponding to a specific capacity of 16 gpm per foot. During the step test, the drawdown was about 5.6' at a pumping rate of 202 gpm, resulting in a specific capacity of 36 gpm per foot. The Beirshenk plot of the data is provided in Figure 2. From this plot, B is calculated to be 0.0217 and C is 0.00003. These values suggest that the well could produce over 900 gpm with the available drawdown. It is unlikely that the efficiency of a 30+ year old well would be more than double that when it was new. It is more likely that the step test has over-estimated the capacity of this well due to the inability of the current pump to adequately stress the well. When a well is not adequately stressed during the step test, the

turbulent flow term (CQ^2) may be underestimated. The step test did, however, indicate that the performance of the Topock 2 well has not declined dramatically since it was drilled. It remains a fairly efficient well, likely capable of producing at least 400 gpm.

Topock 3 (SWW-2) Test Results

The Topock 3 well was pumped in a series of four steps at rates ranging from 19 to 200 gpm (Figure 3). The maximum drawdown observed was about 49.5'. In contrast to Topock 2, the Topock 3 well appears to be no longer efficient. The driller's report from 1974 notes a drawdown of 10' at a pumping rate of 600 gpm, resulting in a specific capacity of 60 gpm per foot. During the step test, the drawdown was about 49.5' at a pumping rate of 200 gpm, resulting in a specific capacity of 4 gpm per foot. The pump exhibited surging, indicating intermittent cavitation due to lack of sufficient water depth above the pump intake.

The well was originally drilled to a depth of 250', with perforated casing from 88' to 130', 150' to 190', and 210' to 250'. It is assumed that this was the condition of the well when it was originally tested at 600 gpm. It was reported that the well was found to produce poor quality water and at some point the bottom 100' of the well were cemented shut. There is no record of what effect this had on the capacity of the well.

A video of the well taken by the Arizona Department of Environmental Quality (ADEQ) as part of their Topock Groundwater Study shows blank casing to a depth of 114' with stainless steel wire-wrapped screen from 114' to about 128' (ADEQ 2006). The well was reported by ADEQ to be blocked at 128' with sediment in the bottom and what appears to be a piece of railroad track iron extending about 1 foot up out of the bottom of the well. Based on the well video (ADEQ 2006), the stainless steel screen appears to be mostly open and in good condition, but the mild steel casing above the screen appears to be badly corroded and in relatively poor condition. In its current condition, the maximum production rate for this well is slightly less than 200 gpm. The Beirshenk plot of the data is provided in Figure 4. From this plot, B is calculated to be 0.048 and C is 0.001.

Conclusions

Step drawdown tests of approximately 1.5 hour duration were conducted on consecutive days at wells Topock 2 and Topock 3. These tests utilized the existing 200 gpm pumps installed in the wells. The Topock 2 well appears to be fairly efficient such that the 200 gpm pump installed in the well is not capable of producing enough drawdown to sufficiently stress the well for an aquifer test. The Topock 3 well is inefficient such that it can be pumped dry at a flow rate of 200 gpm. The two wells are located about 70' apart. There would be hydraulic interference if both wells were pumped at the same time. Consequently, it is likely that not much more water could be produced by pumping both wells than by pumping Topock 2 alone.

Executive Summary

Additional soil and groundwater characterization activities were conducted as part of Phase 2 of the Pacific Gas and Electric Company (PG&E) East Ravine-Topock Compressor Station (ER-TCS) groundwater investigation in the areas of the East Ravine and Topock Compressor Station (TCS) to collect supplemental information regarding groundwater occurrence, groundwater quality, and potential contaminant sources. As with the prior investigation phase conducted in 2009 (Phase 1), data summary teleconferences (referred to as screen calls) were conducted during this investigation to discuss field data, available laboratory analytical results, and the path forward for the investigation with the agencies, stakeholders, interested Tribes, and members of the Technical Review Committee (TRC). A total of 11 screen calls were held from March 2011 through September 2012.

During the Phase 2 activities, CH2M HILL installed an additional 20 groundwater monitoring wells within the unconsolidated alluvium and consolidated bedrock using 16 boreholes at 11 investigation sites. Soil samples were collected at six investigation sites in the area of the TCS and at one site in the East Ravine. Hydraulic testing, including flow characterization within three bedrock boreholes and a constant-rate extraction test at one of these locations, was conducted to refine the understanding of groundwater occurrence and flow within the saturated bedrock. Phase 2 field investigation activities were completed in July 2012, and all new monitoring wells have been incorporated into the Topock site-wide groundwater monitoring program and are being sampled quarterly. Results from the ER-TCS groundwater investigation have also been incorporated into the design of the groundwater remedy (e.g., two injection wells were located on the compressor station to address hexavalent chromium [Cr(VI)] concentrations in the alluvial groundwater underneath the station).

Summary of Key Findings

1. **Refined understanding of hydrogeology.** The depth and location of the contact between saturated unconsolidated sediments and consolidated bedrock has been refined based on lithologic data collected from the boreholes drilled. The depth to bedrock beneath the TCS was found to be deeper than previously estimated, which indicates a larger area of saturated alluvium in this area than previously estimated. Bedrock

core recovered indicates that Miocene conglomerate bedrock is present beneath a portion of TCS with decreasing thickness to the south, where metadiorite bedrock is observed directly beneath the conglomerate. The occurrence of the metadiorite bedrock was confirmed at investigation sites in the East Ravine and to the south. Figures 3-1 through 3-5 present the updated hydrogeologic information.

2. **Refined understanding of groundwater occurrence in bedrock.** Hydraulic data collected during this investigation suggest that groundwater occurrence in the bedrock is within relatively widely spaced, discrete fractures. Although the rock is highly fractured in some zones, most of the fractures are gouge filled. The gouge filled fractures and bulk rock matrix do not readily transmit water. This flow regime, which is typical of crystalline bedrock systems, is consistent with the existing conceptual site model for the East Ravine area. As inferred based on the borehole flow characterization testing and analysis of the bedrock core recovered, the locations of inflow to the boreholes are generally not correlated with highly fractured zones or zones of poor quality rock, but rather with discrete fractures in relatively competent rock. Based on the widespread distribution of Cr(VI) in East Ravine bedrock, the discrete fractures observed in the boreholes may form an interconnected network. Constituents can travel relatively quickly through networks of interconnected fractures. Compared to a porous media aquifer where water occupies all the spaces between the grains in the porous matrix, a relatively small amount of water is required to fill a sparse fracture network in a block of low porosity bedrock. Based on estimates of specific capacity, developed from measurements of drawdown during well development and routine well sampling, which provide a qualitative means of comparing the production rate of the different wells, the bedrock produces little groundwater relative to the nearby unconsolidated aquifer (See Attachment B2). The two bedrock wells with the highest specific capacity estimates are located near the contact between the bedrock and saturated unconsolidated sediments, which might indicate hydraulic connection with the unconsolidated aquifer. Contoured groundwater levels collected during this investigation confirm previous estimates of groundwater gradient, which is generally to the northeast along the axis of East Ravine and to the north from the TCS. In fractured bedrock, groundwater tends to follow conductive fractures so that the direction of groundwater movement through a fracture or a network of fractures might not be directly down gradient. Vertical gradients at well pairs within the saturated bedrock and between the bedrock and unconsolidated aquifer are all upward.

3. **Refined extent of Cr(VI) contamination in groundwater.** Multiple groundwater sampling events were conducted as a part of this investigation, and the extent of Cr(VI) contamination in the East Ravine and TCS areas has been further defined both laterally and vertically. Key observations regarding Cr(VI) contamination in new wells is described as follows, and Figures 3-2 through 3-6 and 3-8 illustrate the extent of Cr(VI) in groundwater:

    a. **East Ravine area.** With the exception of concentrations detected in the parts per million in the western area of the East Ravine (Site H, MW-70BR-225), Cr(VI) concentrations observed in the new wells are similar to the previously installed wells and do not indicate any previously unknown groundwater hotspots. The easternmost well (Site I, MW-73-80) had Cr(VI) concentrations near alluvial aquifer background (a background concentration for Cr(VI) concentrations in bedrock has not been developed).

    b. **TCS site.** Elevated levels (part per million), including the highest concentrations of Cr(VI) that have been detected on the site, were found in the alluvial aquifer beneath the TCS. The bedrock beneath the central portion of the station did not contain Cr(VI). Low levels of Cr(VI) were found where the water table occurs in bedrock at the southern edge of the TCS, but were not detected at the southernmost location (Site J, MW-74-240).

Conclusion

Data collected during Phase 2 of this ER-TCS investigation have resulted in the addition of two alluvial aquifer injection wells near the compressor station, and a bedrock extraction well near MW-70 to the remedial design. In addition, the data from the Phase II investigation show that the overall design of the final groundwater remedy in East Ravine, which relies on pumping from bedrock, do not need to be modified.

As communicated by the Department of Toxic Substances Control (DTSC) in a May 10, 2012, email (DTSC, 2012), Phase 2 field investigation activities are complete with the exception of Site H (MW-70 well series), where the agencies have directed PG&E to conduct additional characterization to determine the vertical extent of Cr(VI) in groundwater. This work and any further well installation will be considered as part of the groundwater monitoring program to be established as part of the groundwater remedy.

1.0 Introduction

Pacific Gas and Electric Company (PG&E) is addressing chromium in groundwater at the Topock Compressor Station (TCS) located in San Bernardino County, approximately 15 miles to the southeast of Needles, California, as shown in Figure 1-1. Investigative and remedial activities at the TCS are being performed under the Resource Conservation and Recovery Act (RCRA) corrective action process, as well as the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), under agreements with the California Environmental Protection Agency, Department of Toxic Substances Control (DTSC, and the United States Department of the Interior (DOI), respectively.

This technical memorandum documents groundwater investigation and associated activities in two areas of the Topock site: 1) the ravine area east of the TCS designated as Area of Concern (AOC) 10 (hereafter referred to as the East Ravine), and 2) the area beneath the TCS site. Specifically, this technical memorandum documents the findings of the investigation activities as outlined in the *Revised Addendum to the Revised Work Plan for East Ravine Groundwater Investigation* (Work Plan Addendum) (CH2M HILL, 2010). The investigation activities defined in the Work Plan Addendum are collectively referred to in this technical memorandum as the East Ravine-Topock Compressor Station (ER-TCS) groundwater investigation, or Phase 2. Phase 1 activities, also referred to as the East Ravine Groundwater Investigation (ERGI), were conducted in 2009 in accordance with the *Revised Work Plan for East Ravine Groundwater Investigation* (CH2M HILL, 2008). The findings associated with the ER-TCS (Phase 2) investigation are presented in this technical memorandum as an addendum to the Phase 1 work, which are documented in the *Summary of Findings Associated with the East Ravine Groundwater Investigation* (East Ravine Report) (CH2M HILL, 2009a).

This technical memorandum was initially submitted to DTSC and DOI on November 15, 2012 and has been revised based on comments received from the agencies (comments and summary of clarification discussion provided in Attachment F). Primary revisions to the document include the following:

- Key investigation data collected during Phase 1 of the investigation (e.g., boring logs, well construction information, etc.) has been brought forward from the Phase 1 summary report and included in this technical memorandum.
- The scope of laboratory analytical results for groundwater samples included in this document has been expanded to include results from Phase 1 and groundwater monitoring program (GMP) events conducted subsequent to Phase 1. This document now includes laboratory analytical results through March 2013, which are the most recently published GMP data.
- The presentation and discussion of groundwater analytical results for key constituents has been modified to address average water quality conditions observed over the entire duration of the investigation (Phase 1, Phase 2, and GMP events conducted from Phase 1 through March 2013). The presentation of data also considers minimum and maximum concentrations observed during this timeframe. The presentation and summary of data for specific groundwater sampling events are presented in the associated GMP reports.
- The scope of laboratory analytical results for soil samples included in this document has been expanded to include results from borings installed during Phase 1; however, the detailed discussion of the soil analytical results in the context of other soil samples collected in the investigation area as part of the Soil RCRA Facility Investigation/Remedial Investigation (RFI/RI) has been deferred to reports associated with the RFI/RI. Discussion of soil data in this document has been focused to how these data support the groundwater conceptual model for the ER-TCS Area.

Groundwater monitoring wells were installed at 11 sites during the Phase 2 of this groundwater investigation to provide additional groundwater and soil characterization data for the Topock site. This additional information supplements the existing data set collected from monitoring wells installed at the eight Phase 1 sites (note that one of the Phase 1 investigation sites, Site F, was also included in Phase 2 well installation activities). The majority of Phase 2 well installation activities were conducted between March 2011 and September 2011, while groundwater sampling and hydraulic testing activities specific to this investigation continued through February 2012. Well installation and testing activities for one location (Site K, MW-72BR-200) were conducted in June and July 2012. As stated in the Work Plan Addendum, the primary objectives of the Phase 2 investigation were to accomplish the following:

- East Ravine area
  - Define the nature and extent of the groundwater contamination within the bedrock and/or alluvium.
  - Identify the source(s) of bedrock groundwater contamination.
- TCS site
  - Define the nature and extent of the groundwater contamination within the bedrock and/or alluvium.
  - Characterize hydrogeologic conditions within the bedrock and alluvium.
  - Determine whether groundwater contaminant sources are present within the TCS boundary that could affect the immediate area or surrounding land, including the East Ravine area.

In addition to these objectives, data and associated findings from the investigation have been considered in the design of the final groundwater remedy.

1.1 Approvals and Authorizations

The ER-TCS groundwater investigation was executed in conformance with the following approvals and authorizations:

- DTSC approval (DTSC, 2011) of the Work Plan Addendum subject to the condition set forth in the Mitigation Monitoring and Reporting Program (MMRP) adopted as part of the January 31, 2011 *Final Environmental Impact Report for the Topock Compressor Station Groundwater Remediation Project* (Final EIR) (DTSC, 2011).
- DOI, Bureau of Land Management (BLM), United States Fish and Wildlife Service (USFWS), and United States Bureau of Reclamation (BOR) acceptance of the Work Plan Addendum and approval for implementation subject to conditions set forth in the letter (DOI, 2011).
- Agreement to Amend Lake or Streambed Alteration Agreement (Notification No. 1600-2005-0140-R6 between the California Department of Fish and Wildlife (CDFW) and PG&E (CDFW, 2007).
- Pre-construction and post-construction biological surveys were conducted in compliance with the *Programmatic Biological Assessment for the Pacific Gas and Electric Topock Compressor Station Remedial and Investigative Action* (PBA) (CH2M HILL, 2007).

1.2 Technical Memorandum Organization

This technical memorandum has been organized to correspond with the structure of the East Ravine Report so that the work summary conducted as part of the ER-TCS groundwater investigation can be easily referenced with the data collected as part of the 2009 ERGI. The rest of the memorandum is organized in the following manner:

- **Section 2** summarizes the borehole drilling, well installation, borehole characterization, hydraulic testing, groundwater sampling, and associated field activities performed.
- **Section 3** presents the results of the drilling investigation, including lithologic observations, borehole flow characterization, borehole groundwater sample data (screening-level), soil sample data, groundwater monitoring well data, and hydraulic testing data.

- **Section 4** summarizes the refinements made to the conceptual site model presented in the East Ravine Report by incorporating the ER-TCS investigation data and presents conclusions and recommendations for consideration in the design of the final groundwater remedy.
- **Section 5** provides a list of works cited in this technical memorandum.

2.0 Summary of Field Activities

This section summarizes the borehole drilling, well installation, borehole characterization, hydraulic testing, groundwater sampling, and associated field activities performed in accordance with the Work Plan Addendum. Phase 2 investigation activities were initiated at Sites 2 through 6, and F, H, K, and L, which were designated in the Work Plan Addendum as "primary" investigation locations (see Figure 2-1). Based on the data collected from the primary investigation locations, PG&E was directed by DTSC and DOI to expand the investigation to Sites I and J, which are designated as "contingency" locations in the Work Plan Addendum. During Phase II investigations, well installation activities were not conducted at contingency Sites 1, I-Alt, or J-Alt.

In most cases, multiple monitoring wells have been installed at each investigation site. Throughout the remainder of the document activities and data will be presented according to the specific monitoring well name and not the investigation site name (with the exception of soil data presentation). For reference, the investigation site names from Phases 1 and 2 and the corresponding monitoring well numbers are defined below, and in more detail on Table 2-1:

Site Name	Monitoring Well Series	Well Installation Phase(s)
A	MW-58 wells	Phase 1
B	MW-57 wells	Phase 1
C	MW-61 well	Phase 1
C-Alt	MW-64 wells	Phase 1
D	No wells installed	--
E	MW-62 wells	Phase 1
E-Alt-1	No wells installed	--
E-Alt-2	MW-63 well	Phase 1
F	MW-60 wells	Phases 1 and 2
G	MW-59 well	Phase 1
H	MW-70 wells	Phase 2
I	MW-73 well	Phase 2
I-Alt	No wells installed	--
J	MW-74 well	Phase 2
J-Alt	No wells installed	--
K	MW-72 wells	Phase 2
L	MW-71 well	Phase 2
1	No wells installed	Phase 2
2	MW-67 wells	Phase 2
3	MW-68 wells	Phase 2
4	MW-69 well	Phase 2

Site Name	Monitoring Well Series	Well Installation Phase(s)
5	MW-65 wells	Phase 2
6	MW-66 wells	Phase 2
MW-23	MW-23 wells	Phase 1 (reconstruction only)

Figure 2-1 presents the Phase 1 and Phase 2 primary and contingency investigation sites as originally shown in the Work Plan and Work Plan Addendum, and the groundwater monitoring wells installed at each site. Table 2-1 summarizes key drilling and well installation details. Major elements of the Phase 2 field investigation included the following:

- Site access, preparation, and compliance monitoring
- Drilling and lithologic logging
- Soil sample collection
- Monitoring well installation and development
- Borehole flow characterization
- Groundwater monitoring well sample collection
- Hydraulic testing and monitoring
- Investigation-derived waste management

2.1 Site Access, Preparation, and Compliance Monitoring

An onsite biologist conducted a pre-construction survey before work began and a post-construction survey following the completion of work at each investigation site to assess and document compliance with the PBA. The results of these surveys are provided in the *Biological Resources Completion Report for the East Ravine Groundwater Investigation, Topock Compressor Station, Needles, California* (CH2M HILL, 2012b), which was submitted to BLM and the Havasu National Wildlife Refuge (HNWR) in December 2012. The drilling sites were accessed by the approved, preexisting routes identified in the Work Plan Addendum. No vegetation was cleared during this investigation. No listed species or nesting birds were observed during the pre-activity or post-activity surveys.

Representatives of DTSC, BLM, DOI, HNWR, and Native American Indian Tribes were present during a project initiation meeting held at the TCS on March 15, 2011, immediately before investigation activities were initiated. In addition, representatives of the Fort Mojave Indian Tribe and Colorado River Indian Tribe were present during portions of the work to observe investigation activities.

Each drilling location (including contingency sites) was surveyed for underground utilities prior to work. The surveys included participating in the California Underground Service Alert (USA) mark-and-locate program and using surface geophysics. In addition, soft-clearance excavation techniques were used at all TCS locations (Sites 1 through 6) to comply with site-specific protocols (see Section 2.3).

Compliance monitoring activities associated with the Environmental Impact Report Mitigation Monitoring Reporting Program (EIR MMRP) were conducted continuously during field work associated with the Work Plan Addendum and are documented in the quarterly compliance reports, which are available on the DTSC website for the Topock Project Site.

2.2 Drilling Methods and Lithologic Logging

All drilling and lithologic logging activities were performed under the supervision of a California Professional Geologist. Soil and rock recovered during drilling were logged in accordance with the methods and procedures identified in the Work Plan Addendum. Three different drilling methods were used to install boreholes during the Phase 2 investigation: rotosonic, rotary-core, and air percussion hammer. One track-mounted drilling rig was modified in the field to conduct drilling by each of these methods for all boreholes with the exception of MW-72BR-200, which was drilled using a truck-mounted rig capable of rotosonic and rotary-core drilling. Continuous core was collected from the unconsolidated portion of all boreholes, and from all bedrock intervals of interest (i.e., typically all portions of the borehole deeper than existing boreholes at a given site).

Rotosonic drilling was used to drill through unconsolidated materials above bedrock and within consolidated bedrock when highly disturbed bedrock core was acceptable or to widen boreholes initially drilled using another method. Diamond-bit rotary core drilling with HQ-size tools (3.8-inch diameter) were used to drill through consolidated bedrock when relatively undisturbed bedrock core was required. Air percussion hammer drilling was used to drill through consolidated bedrock when core was not required and the rotosonic or rotary core methods were not practicable (i.e., when an appreciable thickness of bedrock needed to be drilled). Air percussion hammer drilling was used at only one location (within the vadose zone of Site J) while rotary-core and/or rotosonic drilling was used at all other locations. All freshwater that was used for drilling was collected from the TCS freshwater storage tanks, which are filled by supply wells on the Arizona side of the Colorado River.

Attachment A-1 describes the drilling and construction of each borehole installed during this investigation. The core obtained during this investigation was used to prepare the lithologic logs provided in Attachment A-2, and key sections of the core have been retained at the site as part of the Topock core archive. Section 2.4 discusses well installation rationale and details, and Section 3.1 discusses site lithology and hydrostratigraphy.

2.3 Soil Sample Collection

Soil samples were collected at Sites 1 through 6 and H based on the approach presented in the Work Plan Addendum. The Work Plan Addendum indicated that soil samples should be collected from Site J if there were any alluvial sediment above bedrock; however, because bedrock was encountered at the ground surface, no soil samples were collected at Site J. All soil samples were collected from the rotosonic core using the standard operating procedures established for previous phases of soil sample collection at the site with the exception of samples collected in the upper 3 to 6 feet of all sites on the TCS (Sites 1 through 6), which were collected during the soft-clearance excavation activities required to clear the boreholes for underground utilities. Specifically, the three shallowest soil samples (i.e., intervals of 0 to 0.5 foot, 2 to 3 feet, and 5 to 6 feet below ground surface [bgs]) at Sites 1, 2, 3, and 6 and the two shallowest soil samples at Sites 4 and 5 were collected during soft-clearance activities. All deeper samples at each location were collected from the rotosonic drill core with the exception of the 5- to 6-foot bgs sample at Site 5, which could not be collected due to boulder concentration (i.e., lack of soil), and the 9- to 10-foot bgs sample from Site 6, which could not be collected due to lack of core recovery. Deeper samples at Site 1 were not collected because a borehole was not drilled at this location.

The procedure used to collect soil samples during soft-clearance excavation on the TCS, which is based on the standard operating procedures established for previous phases of soil sample collection at the site, is as follows:

1. Conduct excavation using pressurized water, as necessary, and vacuum. Once the borehole has been excavated to a depth 0.5 foot shallower than a planned sample collection depth, excavation is continued using vacuum only (no water) to the depth of sample collection.
2. Using hand tools, an appropriate volume of soil required for all planned analyses (except volatile analyses) is collected and transferred to a stainless-steel mixing bowl and for subsequent homogenization.
3. The tool required for volatile aliquot collection (e.g., disposable syringe) is then used to collect a sample from a freshly exposed surface at the bottom of the borehole. This is conducted by reaching down the hole by hand; however, once the bottom of the borehole can no longer be reached, an extension tool (e.g. hand auger) is used to collect fresh soil, and the aliquot is collected at the surface from the least disturbed portion of the recovered soil.
4. The soil collected for the nonvolatile analyses are homogenized and distributed to the appropriate sample containers.

Section 3.4 presents the results of laboratory analysis of the soil samples.

2.4 Monitoring Well Installation and Development

In accordance with the logic presented in Section 2.1 of the Work Plan Addendum, each borehole installed during the Phase 2 investigation was used to install monitoring well(s), or as is the case for select bedrock boreholes, was left open for subsequent testing and groundwater monitoring activities. For locations where screening-level characterization data were collected during drilling or as a part of testing activities, monitoring well design was

established in consultation with the DTSC, DOI, and other stakeholders. Well design was based on evaluation of lithologic data from recovered core or drill cuttings, borehole flow characterization (hydrophysical data), and screening-level groundwater quality data. Once installed, each well was surveyed for location, ground surface elevation, and groundwater level measurement reference elevation. The majority of well installation and development activities were conducted from March 2011 to September 2011 with the installation and development of MW-72BR-200 taking place in June and July 2012.

The materials and methods used for installing and developing groundwater monitoring wells are presented in this section. Table 2-1 summarizes well installation details, and Attachment A-3 provides the well construction diagrams. Although drilling and well installation activities conducted as part of the Work Plan Addendum are exempt from the requirement to obtain well installation permits from San Bernardino County pursuant to the CERCLA permitting exemption, the substantive requirements associated with the permits were followed. Further, well completion reports were filed with the California Department of Water Resources and San Bernardino County by the drilling company (Boart-Longyear) and are provided in Appendix A-4.

Conventional, single-screen monitoring wells and nested monitoring wells were constructed during the investigation. Nested monitoring wells were used when it was determined that two separate monitoring zones were of interest in one borehole. The well casing, screen, and borehole completion materials were the same for the construction of both well types with the exception of the specialized centralizers that are required for nested well construction. Conventional monitoring wells were constructed to monitor intervals within the unconsolidated sediments or within the shallowest portion of saturated bedrock at MW-67-185, MW-69-195, MW-70-105, MW-71-80, MW-73-80, MW-74-240, and MW-71-35; nested monitoring wells were constructed to monitor two separate intervals within the unconsolidated sediments at MW-67-225 and MW-67-260, MW-68-180 and MW-68-240, MW-65-160 and MW-65-225, and MW-66-165 and MW-66-230. All single casings were constructed within a minimum 6-inch-diameter rotosonic drill casing, which was retracted as the well was constructed. Nested casings were installed within a minimum 10-inch diameter rotosonic drill casing. Each well was constructed with threaded, 2-inch-diameter, schedule 40 polyvinyl chloride (PVC) casing and screen (0.02-inch factory-slotted). Filter pack material consisting of no. 3 Monterey silica sand was installed around the screen and a minimum of 2 feet above the top of the screened interval with an additional 0.5 to 1 foot of no. 60 transition sand. The screened interval was then sealed from the remainder of the borehole with approximately 5 feet of bentonite chips. Grout was installed via positive pressure tremie from the top of the bentonite seal up to near ground surface displacing water that had collected in the borehole above the bentonite seal.

Boreholes MW-68BR-280, MW-66BR-270, MW-60BR-245, MW-70BR-225, and MW-72BR-200 were drilled into bedrock through permanent conductor casing. For each of these boreholes, the permanent conductor casing was installed to isolate deeper portions of the borehole from shallower intervals of the aquifer, which were monitored by separate wells. Specifically, the deeper boreholes at MW-68BR-280 and MW-66BR-270 were isolated from the unconsolidated portion of the aquifer, and deeper boreholes at MW-60BR-245, MW-70BR-225, and MW-72BR-200 were isolated from shallower portions of the bedrock aquifer. These boreholes were not completed with permanent well screen and casing in addition to the conductor casing, and remain as open bedrock boreholes for subsequent testing and groundwater monitoring, as determined necessary. Five inch diameter PVC conductor casing was used at MW-60BR-245, and MW-70BR-225, and 6-inch diameter was used at MW-72BR-200. Five inch diameter steel conductor casing was used at MW-68BR-280 and MW-66BR-270 due to the depth of installation. All conductor casings were constructed with a minimum 2-inch annulus between the casing and the borehole wall. Portland cement grout was used to seal the annulus between the conductor casing and the borehole wall from the total depth of installation to the ground surface.

Small volumes of drilling fluids and/or grout were observed to “daylight” in the slope nearby the boreholes during the installation process for wells at the MW-60 cluster and the MW-72 cluster. The work area at each of these sites is situated on an artificial pathway/road that was created on the edge of a steep slope. Therefore, a steep slope that drops to a lower elevation is located approximately 10-20 feet from the borehole. Shallow, gravel containing fill comprises the upper 8 and 13 feet at MW-60 and MW-72, respectively. When the boreholes are filled with fluids, either for the purpose of drilling or grouting, the open pore spaces in the fill that are typically dry

provide a conduit for these fluids to migrate away from the borehole. The migration of fluids during drilling in the vadose zone is not uncommon; however, because most drill sites are not adjacent to a steeply dipping slope, the migration of fluids isn't typically visible at the ground surface. Due to the proximity of the steeply dipping slopes at these two sites, the fluids were visible on the surface of the slope. At MW-60 approximately 10-20 gallons of grout accumulated at the base of the slope during the installation the MW-60-125 well casing (during Phase 1), and a minor amount grout was observed on the slope during the conductor casing installed for MW-60BR-245 (Phase 2). The grout that accumulated near MW-60 was removed from the base of the slope following work. During initial drilling of both MW-72 boreholes, small areas (less than one square foot) became noticeably wet, but fluids did not accumulate on or at the base of the slope. Grout was not observed on the surface of the slope near MW-72.

After well construction or borehole drilling activities were completed, each well or borehole was developed to remove fluids introduced during drilling and installation. All monitoring wells were developed using a combination of surging, bailing, and pumping, as necessary. All open boreholes were initially flushed from the bottom of the hole using freshwater to remove drilling cuttings and then developed using a combination of bailing and pumping, as necessary. During development, temperature, pH, specific conductance, oxidation reduction potential (ORP), dissolved oxygen, and turbidity were measured using field instruments. Well development was continued until the minimum purge volume (based on estimates of water loss during drilling) had been removed and field water quality parameters had stabilized in ranges indicative of groundwater (i.e., different water quality signature than that from the source water used during installation). Once development was complete, screening-level groundwater samples were collected for analysis at the offsite laboratory for hexavalent chromium [Cr(VI)] and Title 22 metals (results are discussed in Section 3.3).

2.5 Borehole Flow Characterization

Borehole flow characterization testing was conducted in the open bedrock boreholes at MW-60BR-245, MW-70BR-225, and MW-72BR-200 to identify groundwater producing fractures within the metadiorite bedrock. This testing was not conducted at Sites 3 and 6 due to the relatively small length of open borehole (approximately 20 feet of open borehole at these locations compared to the 80 to 100 feet at MW-60BR-245, MW-70BR-225, and MW-72BR-200). Based on the low range of inflow rates detected during the ERGI investigation, borehole dilution testing (here forth referred to as hydrophysical testing or hydrophysics) was selected for characterization during the Phase 2 investigation. Hydrophysical testing was conducted by RAS, Inc. in October and November 2011 at MW-60BR-245 and MW-70BR-225, and during July 2012 at MW-72BR-200.

Hydrophysical testing uses the contrast in fluid electrical conductivity (FEC) and temperature between deionized water and groundwater in the formation to identify intervals of groundwater inflow and outflow in the borehole. The testing is conducted in two phases to characterize flow under both ambient and, subsequently, induced flow or pumping conditions.

During testing under ambient flow conditions, higher FEC formation water within the borehole is replaced with deionized water (FEC near zero), taking care to maintain static water levels during deionized water emplacement. After the deionized water was emplaced, the rates and depths where higher FEC groundwater flows from the formation into and out of the borehole were logged over time using a specialized, down-hole FEC measurement tool.

Following ambient flow characterization, testing was conducted in a similar manner under induced flow (i.e., pumping) conditions to increase the probability of detecting conductive intervals that may not be identified in the ambient flow condition. Due to the location of conductive intervals identified during ambient flow characterization in each of the three boreholes, induced flow testing was conducted using a submersible pump placed near the bottom of the borehole. At MW-60BR-245, where constant rate pumping was not practicable due to low borehole yield, induced flow testing was conducted by removing a slug of water from the borehole and logging the FEC into the borehole during recovery. The data collected were analyzed to evaluate intervals of inflow and outflow in the borehole during well production, in conjunction with drawdown data, so that the flow rate and hydraulic conductivity values for each zone and cumulative flow rate within the borehole could be estimated.

Depth-specific groundwater samples were collected from the boreholes at MW-60BR-245 and MW-72BR-200 where multiple flow intervals were identified through the field analysis of the ambient and induced flow hydrophysical data. The depth-specific samples were collected using a wireline straddle packer tool to isolate fractures in the interval of interest. This tool consists of bladder pump assembled between two inflatable packers, and it is operated on a wireline. With the sample interval identified, the straddle packer tool is moved into place, the packers are inflated, and the zone is purged and sampled using the bladder pump. With only one interval of inflow identified in MW-70BR-225 the straddle packer tool was not necessary, and the groundwater sample was collected from the pump discharge at the conclusion of induced flow testing. Samples collected during borehole flow characterization testing were analyzed for Cr(VI) and Title 22 metals at the offsite laboratory. Sections 3.2 and 3.3 summarize the testing activities and results conducted at MW-60BR-245, MW-70BR-225, and MW-72BR-200.

2.6 Groundwater Monitoring Well Sampling

Groundwater monitoring wells and exploratory boreholes installed during the Phase 2 investigation were sampled during monthly sampling events conducted from June through November 2011. Each well was added to these events as installation was completed. A contemporaneous groundwater monitoring event was conducted in December 2011, which included all wells then installed as part of the Phase 2 investigation and all wells installed during the Phase 1. All Phase 1 and 2 wells were subsequently sampled in February, May, and September 2012 as part of the quarterly events associated with the Topock Groundwater Monitoring Program (GMP). The initial sample from MW-72BR-200, which was installed and tested in June and July 2012, was collected during the September 2012 event. Table 2-2 summarizes the groundwater sampling events conducted as part of the entire duration of the investigation (Phase 1, Phase 2, and GMP events conducted from Phase 1 through February 2013), and Section 3.5 summarizes the laboratory analytical results.

2.7 Hydraulic Testing and Monitoring

Hydraulic data were collected during Phase 2 to assist with refining the conceptual model for the East Ravine and TCS areas. Hydraulic testing and water level gauging activities were performed in January 2012. A constant-rate extraction test was performed at Site H (MW-70BR-225) to evaluate the effect of pumping in this well on nearby wells completed in the bedrock and unconsolidated aquifer. During the test, the MW-70BR-225 well was pumped at a sustained rate of approximately 9.5 gallons per minute (gpm) for a period of approximately 12 hours. Water levels were monitored in the pumping well (MW-70BR-225) and 20 observation wells using pressure transducers with data-logging capability: MW-12, MW-48, MW-23-060, MW-23-080, MW-57-070, MW-57-185, MWR-58BR[1], MW-59-100, MW-60-125, MW-60BR-225, MW-61-110, MW-62-065, MW-63-065, MW-64BR-UPR , MW-68-180, MW-69-195, MW-71-35, MW-72-080, MW-73-080, and MW-74-240. In addition, another eight observation wells were monitored manually during the test: MW-65-160, MW-65-225, MW-66-165, MW-66-230, MW-67-185, MW-67-225, MW-67-260, MW-68-240, MW-68BR-280, and MW-70-105. Groundwater samples were collected from the pump effluent at the beginning, during, and end of the 12-hour test for analysis at the onsite Interim Measures (IM) No. 3 laboratory. Water level measurements were collected to evaluate horizontal and vertical gradients within wells installed in the East Ravine and TCS areas over a period of approximately 1 hour immediately prior to the start of the MW-70BR-225 constant-rate extraction test. This “water level snapshot” was collected using manual depth-to-water measurements.

2.8 Investigation-Derived Waste Management

Investigation-derived waste was managed in accordance with the procedures detailed in the Work Plan Addendum. All waste generated during the 2011 and 2012 investigation was non-hazardous. Solid and liquid wastes generated during this investigation were temporarily stored at the work area in hoppers (drill cuttings) and portable tanks (liquids), and then transferred to lined roll-off bins and storage tanks located on the decontamination pad. Waste from respective storage tanks and roll-off bins were sampled for waste characterization. Disposal characterization samples were submitted to certified laboratories for the same analyses

[1] The packer installed in the MW-58BR borehole was not functional at the time of the test. Therefore, the water level monitored during the test represents the entire borehole.

during previous drilling projects, including Title 22 metals, mercury, and percent moisture for drill cuttings and total organics and Title 22 metals for liquids.

Based on the waste characterization results, liquid waste was either transferred to the IM No. 3 groundwater treatment facility for onsite treatment and injection in compliance with California Regional Water Quality Control Board (RWQCB) Order No. R7-2006-0060 (2006), or transported to an offsite treatment facility: Liquid Environmental Solutions (LES), located in Phoenix, Arizona. Typically, waste that was transported to LES had detections of total petroleum hydrocarbons (TPH) (both diesel and motor oil range), which cannot be treated at the IM No. 3 treatment facility. It is assumed that the TPH introduced to the waste stream during the decontamination of the drilling rig and associated equipment, which are prone to minor leakage (e.g., motor oil or hydraulic oil). A total of approximately 25,000 gallons was treated at IM No. 3 and 20,000 gallons was transported offsite and treated at LES. Waste that was shipped to LES was treated under PG&E's profile number—202805.

Approximately 100 cubic yards of drill cuttings were generated during this investigation. Based on the composite soil characterization sample results, dry drill cuttings were either stored onsite or transported offsite to the US Ecology, Inc., Beatty, Nevada, Hazardous Waste Treatment and Disposal Facility (all waste shipped to the facility was non-hazardous). Waste that was stored onsite was stockpiled in a designated location where soil will be used for future uses. Waste that was shipped offsite for disposal had concentrations that were at or above the established screening levels for the Topock site for either TPH (motor oil range) and/or metals or had physical properties that were not conducive to storage (i.e., rock flour suspended in thick slurry). Approximately 20 cubic yards of drill cuttings were stockpiled onsite for future use, and 80 cubic yards of drill cuttings were transported offsite to the US Ecology disposal facility. Waste that was shipped offsite for disposal was shipped and/or disposed under PG&E's profile number—070181764-0.

Incidental trash was removed from the work area daily and was transferred to a standard trash bin at the TCS for offsite disposal.

3.0 Investigation Results

This section presents the results of the soil, hydrogeologic, and water quality sampling and testing activities conducted as part of the investigation. Section 4.0 discusses the integration of all of the available data from the East Ravine area investigations into the TCS site hydrogeologic conceptual model.

3.1 Lithology and Hydrostratigraphy

A primary objective of this investigation was to further characterize the site hydrogeologic conditions in the East Ravine and TCS areas. Table 3-1 summarizes the lithology encountered during Phase 1 and Phase 2 well installation. Five hydrogeologic cross-sections have been prepared to illustrate the lithologic and hydrogeologic data collected during drilling and well sampling. These cross-sections present the interpreted hydrostratigraphy, well-screen intervals, primary lithologic contacts, Cr(VI) laboratory results for soil samples collected during Phases 1 and 2, and the average Cr(VI) laboratory analytical results from select wells sampled over the entire duration of the investigation (these results further discussed in Section 3.5). Figure 3-1 shows the locations of these cross-sections, and Figures 3-2 through 3-6 present the hydrogeologic cross-sections.

Following are the key findings from incorporating the lithologic data collected during the Phase 2 investigation:

- The depth to bedrock beneath the TCS was found to be deeper than previously estimated, which indicates a larger area of saturated alluvium in this area. Figure 3-1 presents a revised estimated contact between the alluvial aquifer and bedrock.
- Saturated alluvium in the East Ravine area was only encountered at MW-71-035 (Site L), where the saturated thickness above conglomerate bedrock was relatively thin. Sediments at this location were relatively fine-grained compared with areas of saturated sediments to the east.
- The contact between conglomerate and metadiorite bedrock was encountered at MW-68BR-280 (Site 3). The interval of degraded cementation in the conglomerate above the contact and the mylonitic structure of the bedrock across this contact was similar to that observed at MW-57-185 (ERGI Site B), which is the only other

place where this contact has been drilled. At both locations, this contact has been observed to yield very little groundwater.

- Metadiorite bedrock was encountered as estimated in all of the drilling sites located in the East Ravine and to the south. The physical nature of the recovered bedrock core was similar to that observed during the Phase 1.

3.2 Borehole Flow Characterization Results

Borehole flow logging was conducted using fluid replacement and fluid-column conductivity logging or "hydrophysical" logging methods at three of the exploratory boreholes (MW-60BR-245, MW-70BR-255, and MW-72BR-200) to identify water-bearing intervals within the bedrock. Testing was conducted under ambient (static-water level) and induced (decrease-water level) flow conditions. Based on the identified intervals of flow, depth-specific groundwater samples were also collected in boreholes MW-60BR-245 and MW-72BR-200 to estimate an interval-specific chromium concentration. Attachment B-1 figures presents a summary of these data.

Several flow zones were identified in borehole MW-60BR-245 above 200 feet in depth; however, the contribution of these shallower intervals to total flow within the borehole was minor. The dominant flow zone was located near the bottom of the borehole at a depth between 236 and 240 feet. Three depth-specific grab samples were collected using packers. Concentrations of Cr(VI) were 130 micrograms per liter (µg/L), 290 µg/L, and 78 µg/L in the shallow, middle, and deep samples, respectively.

Only one flow zone was identified in borehole MW-70BR-255. This interval is located near the bottom of the borehole at a depth of 208 and 220 feet. The flow rate calculated for this interval is the highest of all intervals identified during hydrophysical testing as part of both Phases 1 and 2. Because there was only one flow zone encountered in the borehole, packers were not used to collect depth-specific samples. It was assumed that any sample collected from the well would represent this single, dominant flow zone.

Two primary flow zones and one very minor flow zone were identified in borehole MW-72BR-200. The dominant interval of flow was observed in the middle of the borehole at a depth of approximately 148 to 168 feet and represents about 80 percent of the total flow in the borehole under ambient head conditions. A lesser interval of flow was identified at the bottom of the borehole at a depth of about 195 feet, representing less than 20 percent of the flow in the ambient condition. Depth-specific grab samples were collected from the two primary flow zones (148 to 168 feet and 191 to 198.5 feet) using packers. An attempt at collecting a sample from the minor flow zone near the top of the open portion of the borehole was made, but due to the extremely low rate of recover after pumping, the sample could not be collected. Concentrations of Cr(VI) observed in the middle and deep depth-specific samples were 2 µg/L and non-detect (less than 1 µg/L), respectively.

3.3 Screening-level Groundwater Sample Results

Three types of screening-level groundwater samples were collected during the Phase 2 investigation:

- Depth-specific samples collected during bedrock borehole flow characterization using packers
- Depth-specific samples collected from saturated, unconsolidated sediments during drilling using the Iso-Flow® sampling method
- Pump effluent samples collected immediately following the completion of well development activities (all wells) or during well testing (MW-70BR-225 only)

Some of these screening level data were evaluated by PG&E, DTSC, DOI, and other stakeholders during the field investigation to guide decisions on contingency well installation and well design. Screening-level groundwater samples were analyzed for Cr(VI) and Title 22 metals at either the IM No. 3 onsite laboratory (samples from MW-70BR-225 well testing only) or the offsite Advanced Technologies Laboratory. Groundwater samples obtained during well development, aquifer testing, and borehole flow characterization activities (i.e., grab samples) are considered screening-level data for use as a qualitative assessment of water quality conditions in the aquifer. Therefore, the screening-level samples are not directly compared with laboratory analytical data obtained from completed monitoring wells (provided in Section 3.5). Attachment B-2 summarizes the results of screening-level samples.

As noted in Section 3.2 above, three depth-specific screening level samples were collected from the open bedrock borehole in MW-60BR-245 and two in MW-72BR-200 during the borehole flow characterization testing. Subsequent samples from the MW-60BR-245 and MW-72BR-200 boreholes during the GMP events have generally been within or slightly below the range of concentration represented by the screening level samples. No other depth-specific samples were collected from bedrock during this phase of the investigation.

Depth-specific samples were collected from saturated, unconsolidated portions of the borehole at four locations on the TCS (Sites 2 [BH-67], 3 [BH-68], 5 [BH-65] and 6 [BH-66]) using Iso-Flow® sampling method. Saturated alluvium was also encountered at Site L (BH-71), but there was not enough saturated thickness above bedrock to use the Iso-Flow® method. This method involves pulling back the drive casing and sampling the water in the exposed portion of the borehole using a submersible pump with a rubber diaphragm above the pump to isolate the sampling zone. Where well screens were later installed at the same depths as the Iso-Flow® samples were collected, the concentrations can be compared; however, there is no consistent trend in comparing chromium results. Some Iso-Flow® samples had lower chromium than the subsequent well samples and some had higher. For many other constituents, the variability between Iso-Flow® results and subsequent well results seems to be less than for chromium.

Pump effluent samples were collected after development activities at each completed well or exploratory borehole were completed and during the MW-70BR-225 well test. The post-development data were used for field planning and purged water characterization purposes only. Samples collected during the MW-70BR-225 well test were used to evaluate any trends in the chromium concentration over time during the test and are further discussed in Section 3.6.

3.4 Soil Sample Results

Soil sampling was conducted at each drilling site at the TCS site and at Site H to evaluate the extent of contamination (if present) in the soil (as discussed in Section 2.3). A total of 95 soil samples were collected and analyzed at the laboratory during Phase 2. These data have been incorporated into the existing Soil RFI/RI data set, and specifically, were included in the *Final Soil RCRA Facility Investigation/Remedial Investigation Work Plan* (Final Soil RFI/RI Work Plan; CH2M HILL, 2012a). As presented in the Final Soil RFI/RI Work Plan, soil sample results were compared to the following different screening levels: a) background threshold values (BTVs) and residential and ecological screening levels (if greater than BTV) if collected outside the TCS fence line, and b) commercial screening levels if collected inside the TCS fence line. For the purpose of this report, where analysis of the soil data is focused on the development of the conceptual site model for the ER-TCS areas, results inorganic analytes are compared only to BTVs. For organic analytes, results inside the compressor station fence line were compared to commercial screening levels and results outside the fence line were compared to residential screening levels. If the appropriate DTSC CHHSL was not established, the U.S. Environmental Protective Agency regional screening level was used.

Soil samples were analyzed for metals, inorganics, polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs) and TPH. Soil samples that were collected from fill material were also analyzed for dioxins and furans. Tables for detected analytes in Phase 1 and Phase 2 soil samples are provided as Attachment C-1 of this technical memorandum.

3.4.1 Summary of Hexavalent Chromium, Total Chromium, and Other Metals Results

The following summarizes the soil sample results for Cr(VI), total chromium [Cr(T)], and other metals detected above screening levels at each Phase 2 site where soil samples were collected. Cr(VI) and Cr(T) results for all Phase 1 and Phase 2 soil samples are shown on Figure 3-7.

Site H (BH-70, in which MW-70-105 was installed). Bedrock was encountered at approximately the same depth as the water table at 69 feet bgs; a total of 12 soil samples (including one duplicate sample) were collected above the bedrock/water table. Samples were collected from 0 to 0.5, 2 to 3, 5 to 6, 9 to 10, 14 to 15, 19 to 20, and every 10 feet thereafter to 70 feet bgs. This borehole is located outside the TCS fence line.

- Concentrations of Cr(T) ranged from 7.3 to 66 milligrams per kilogram (mg/kg), five detected concentrations exceeded the BTV of 39.8 mg/kg.

- Cr(VI) was detected above laboratory reporting limits in three samples collected from 0 to 0.5, 2 to 3, and 5 to 6 feet bgs at concentrations of 1.1, 1.6, and 0.43 mg/kg, respectively. Two of the detected concentrations exceeded the BTV of 0.83 mg/kg.
- Aluminum, barium, cobalt, copper, lead, magnesium, manganese, nickel, vanadium, and zinc were also detected above respective BTVs.
- Remaining metals, if detected above laboratory reporting limits, were detected at concentrations below respective BTVs.

Site 1. No boreholes or wells were installed at Site 1; however, soil samples were collected from 0 to 0.5, 2 to 3, and 5 to 6 feet bgs while clearing the location for utilities. This site is located outside the TCS fence line.

- Detected concentrations of Cr(T) ranged from 8.9 to 13 mg/kg, which are below the BTV of 39.8 mg/kg.
- Cr(VI) was not detected above laboratory reporting limits.
- All other metals, if detected above laboratory reporting limits, were detected at concentrations below respective BTVs.

Site 2 (BH-67, in which nested wells MW-67-225 and MW-67-260 were installed). The water table was encountered at approximately 170 feet bgs; a total of 22 soil samples (including two duplicate samples) were collected from ground surface to 160 feet bgs. Samples were collected from 0 to 0.5, 2 to 3, 5 to 6, 9 to 10, 14 to 15, 19, to 20 feet bgs, and every ten feet thereafter to 160 feet bgs. This borehole is located inside the TCS fence line.

- Detected concentrations of Cr(T) ranged from 2.1 to 32 mg/kg, which are below the BTV of 39.8 mg/kg.
- Cr(VI) was detected in one sample at a concentration below the BTV.
- Barium, cobalt, lead, molybdenum, nickel, vanadium, and zinc were detected above respective BTVs.
- Remaining metals, if detected above laboratory reporting limits, were detected at concentrations below respective BTVs.

Site 3 (BH-68, in which nested wells MW-68-180 and MW-68-240 were installed). The water table was encountered at approximately 164 feet bgs; a total of 22 soil samples (including two duplicate samples) were collected from ground surface to 160 feet bgs. Samples were collected from 0 to 0.5, 2 to 3, 5 to 6, 9 to 10, 14 to 15, 19 to 20 feet bgs, and every 10 feet thereafter to 160 feet bgs. This borehole is located inside the TCS fence line.

- Detected concentrations of Cr(T) s ranged from 4.2 to 48 mg/kg. Two detected concentrations (45 mg/kg collected from 139 to 140 feet bgs and 48 mg/kg collected from 149 to 150 feet bgs) slightly exceeded the BTV of 39.8 mg/kg.
- Cr(VI) was not detected above laboratory reporting limit.
- Copper, lead, and nickel were also detected above respective BTVs.
- Remaining metals, if detected above laboratory reporting limits, were detected at concentrations below respective BTVs.

Site 4 (BH-69, in which MW-69-195 was installed). Bedrock was encountered above the water table at 42 feet bgs; a total of 8 soil samples were collected above the bedrock. Samples were collected from 0 to 0.5, 2 to 3, 5 to 6, 9 to 10, 14 to 15, 19 to 20, 19 to 30, and 39 to 40 feet bgs. This borehole is located outside the TCS fence line.

- Detected concentrations of Cr(T) concentrations ranged from 45 to 63 mg/kg, and all detected concentrations exceeded the BTV of 39.8 mg/kg.
- Cr(VI) was detected in one soil sample at a concentration below the BTV.

- Aluminum, calcium, copper, lead, magnesium, manganese, nickel, potassium, vanadium, and zinc were also detected above the BTV.
- Remaining metals, if detected above laboratory reporting limits, were detected at concentrations below respective BTVs.

Site 5 (BH-65, in which nested wells MW-65-160 and MW-65-225 were installed). The water table was encountered at approximately 140 feet bgs; a total of 18 soil samples (including one duplicate sample) were collected between ground surface and 140 feet bgs. Samples were collected from 0 to 0.5, 2 to 3, 5 to 6, 9 to 10, 14 to 15, 19 to 20 feet bgs, and every 10 feet thereafter to 140 feet bgs. This borehole is located inside the TCS fence line.

- Detected concentrations of Cr(T) ranged from 12 to 66 mg/kg. Eight detected concentrations (including one duplicate sample) exceeded the BTV of 39.8 mg/kg
- Cr(VI) was detected in two soil samples at 0.52 mg/kg collected from 0 to 0.5 feet bgs and 0.79 mg/kg collected from 2 to 3 feet bgs, which are below the BTV of 0.83 mg/kg.
- Barium, cobalt, copper, lead, nickel, vanadium, and zinc were also detected above the BTV.
- Remaining metals, if detected above laboratory reporting limits, were detected at concentrations below respective BTVs.

Site 6 (BH-66, in which nested wells MW-66-165 and MW-66-230 were installed). The water table was encountered at approximately 130 feet bgs; a total of 18 soil samples (including two duplicate samples) were collected between ground surface and 130 feet bgs. Samples were collected from 0 to 0.5, 2 to 3, 5 to 6, 9 to 10, 14 to 15, 19 to 20 feet bgs, and every 10 feet thereafter to 130 feet bgs. This borehole is located inside the TCS fence line.

- Detected concentrations of Cr(T) ranged from 5.3 to 29 mg/kg, which are below the BTV of 39.8 mg/kg.
- Cr(VI) were not detected above laboratory reporting limits.
- Lead was also detected above the BTVs.
- Remaining metals, if detected above laboratory reporting limits, were detected at concentrations below respective BTVs.

3.4.2 Summary of TPH and Organics Results

Detected concentrations of PAHs and calculated quantities (Benzo(a)pyrene equivalents, total low-molecular-weight PAHs, and total high-molecular-weight PAHs) were below respective screening levels at BH-67, BH-69, BH-65, BH-66, and BH-70 and were not detected above laboratory reporting limits at Site 1 and BH-68.

PCBs and total PCBs were detected at concentrations below respective screening levels at Sites BH-68, BH-69, BH-65, BH-66, and BH-70, and were not detected above laboratory reporting limits at Site 1 and BH-67.

TPH as diesel and motor oil were detected in soil samples at all sites where soil samples were collected (BH-65 though BH-70, and Site 1) at various depths ranging from 0 and 20 feet bgs, but all detected concentrations were below RWQCB environmental screening levels.

Calculated quantities of dioxins and furans (toxicity equivalents quotient [TEQ]) were below the human-TEQ screening value of 50 mg/kg at all sites where fill was encountered including Site 1, BH-67, BH-68, BH-65, BH-66, and BH-69 (dioxins and furans were not analyzed at BH-70 as fill was not encountered). However, the 0 to 0.5 foot bgs sample from BH-69 exceeded the avian-TEQ and mammal-TEQ ecological screening values (ECVs) and the 2 to 3 feet bgs sample from BH-69 exceeded the mammal-TEQ ECV. No other samples exceeded the ECVs.

Volatile organic compounds were not detected in any of the samples collected with the exception of the surface soil sample at BH-70 where 4-isopropyl toluene was detected and the sample from 60 feet in BH-67 where isopropyl benzene was detected.

3.5 Groundwater Sample Results

This section discusses the results of groundwater samples collected from the wells installed during the ER-TCS investigation. Some of the data discussed in the following sections were provided in previous GMP reports. Analytical results for chromium and other metals are presented on Table 3-2 with average, minimum, and maximum calculations for these data calculated on Table 3-3. The data for general chemistry parameters and field parameters are presented using the same approach on Tables 3-4 through 3-7. Complete laboratory analytical results for groundwater constituents collected as part of the ER-TCS investigation are provided in Attachment C-2.

3.5.1 Distribution of Chromium and Field Measurements

The distribution of Cr(VI) in groundwater is presented on Figure 3-8. This figure shows the minimum, maximum, and average concentrations observed in each well, along with the number of samples in the data set for that well. Tables 3-2 and 3-3 provide the data that are displayed on Figure 3-8. Average Cr(VI) concentration is also presented on the geologic cross sections, Figures 3-2 through 3-6.

The highest concentrations of Cr(VI) in any of the ER-TCS wells were observed in the shallow alluvial well MW-68-180, located in east-central part of the TCS, where Cr(VI) as high as 22,000 µg/L occurred in December 2011. The average Cr(VI) concentration in MW-68-180 is 14,200 µg/L. This well is located near the former "hot well", a concrete tank which acted as a reservoir and surge tank for the jacket water cooling system. Chromium was formerly used as a corrosion inhibitor in the jacket water. Overflows from the hot well are known to have occurred in the past and may be associated with the elevated Cr(VI) concentrations at MW-68-180. Cr(VI) concentrations at MW-68-180 have fluctuated over a relatively wide range, from 1,400 µg/L to 22,000 µg/L. Large fluctuations in concentration are often observed in wells located near contaminant source areas, where steep concentration gradients are present in the aquifer and slight changes in groundwater flow direction result in relatively large changes in concentration in nearby wells. It is also worth noting that the isotopic signature of MW-68-180 is heavier than any of the other ER-TCS wells, with a $\delta^{18}O$ value of minus 7.2 parts per mil (Table 3-5). MW-68-180 is plotted as the green diamond furthest to the right on Figure 3-14, indicating a strong industrial water signature. The TDS in this well is relatively low, averaging 2,450 mg/L.

The highest concentrations of Cr(VI) in any of the ER-TCS wells completed in bedrock were in well MW-70BR-225, where Cr(VI) has ranged from 1,600 to 2,460 µg/L with an average of 2,160 µg/L. As discussed in subsequent sections, MW-70BR-225 produces more water (based on review of specific capacity data and permeability calculations from the hydrophysical testing) and has an isotopic signature that is more similar to alluvial water than most other bedrock wells. This well may be connected through fractures to the relatively nearby alluvial aquifer, and may therefore, produce water that represents a mixture of bedrock and alluvial aquifer water.

As shown in plan view on Figure 3-8 and in cross section on Figure 3-2, the existing monitor wells do not fully define the extent of the area of elevated Cr(VI) in bedrock to the south of the East Ravine. Installation of additional monitor wells further to the south would have required extensive earth works to construct roads and drill pads in extremely steep and rocky terrain. The degree of disturbance that would be necessary to construct additional monitor wells further south was not considered justified. There are no suspected sources of chromium south of the East Ravine and current groundwater gradients are northward. It is therefore unlikely that the plume extends to the south beyond the inferred plume boundary shown on Figure 3-8.

Field parameters shown on Tables 3-6 and 3-7 include specific conductance, temperature, pH, ORP, dissolved oxygen, salinity, and turbidity. These parameters are measured at the time of sampling using portable monitoring equipment. No consistent trends are evident in the ORP or pH data. There are some trends in the specific conductance data from the ER-TCS wells that are consistent with most of the ER-TCS wells. In general, specific conductance is higher and the dissolved oxygen is lower in the deeper wells within each well cluster. This trend is observed in both alluvial and bedrock wells and is consistent with the theory that in this lower portion of the Mohave basin, older connate water is upwelling from the deeper portions of basin. During the eons that it could take for groundwater to move through the basin, the salts are leached from the rocks, increasing specific conductance, and dissolved oxygen is lost through reactions with reduced mineral species. This gradient of

decreasing concentrations from deep to shallow is consistent with the conceptual model of upward movement of groundwater from bedrock to alluvium and from deep to shallower alluvium.

The DTSC geologist questioned whether the fresher water may have infiltrated from surface flows in East Ravine and flushed out the shallow groundwater zone, resulting in lower specific conductance in shallow wells completed in the bottom of the East Ravine. There are four shallow bedrock wells completed in the bottom of East Ravine. From upstream to downstream, these wells are MW-70-105, MW-58BR-UPR, MW-57-70, and MW-62-065. In addition, there are two "perched zone" wells, MW-58-65 and MW-57-50 which are located in the bottom of the ravine but have been dry since shortly after they were drilled. There is only one sample from each of these perched zone wells and it is likely that those samples were compromised due to the inability to develop out all the water that was added during drilling due to low yield. The most reliable data are therefore considered to be from the four shallow bedrock wells. The average specific conductance for these wells in micro-Siemens per centimeter (µS/cm) is 3,050, 11,200, 2,510, and 6,390, respectively. For comparison, the specific conductance of the two shallow bedrock wells in the southern portion of the compressor station are 3,840 µS/cm in MW-69-195 and 1,120 µS/cm in MW-74-240. Shallow bedrock wells further to the south, away from the axis of the East Ravine, appear to have higher specific conductance; 12,100 µS/cm at MW-64BR-UPR, 15,700 µS/cm at MW-72-80, and 11,300 µS/cm at MW-73-80. In conclusion, the four shallow bedrock wells in the bottom of the East Ravine have specific conductance within the same general range as shallow bedrock wells further from the axis of the ravine where focused recharge of surface water would not be expected.

3.5.2 Sample Results for Non-chromium Contaminants of Potential Concern in the ER-TCS Wells

DTSC and DOI have directed that molybdenum, selenium, and nitrate be monitored in the GMP and their associated impacts be considered in future soil and soil to groundwater risk evaluations based on the fact that they were present at concentrations that resulted in risk above a hazard index of 1. Therefore, discussion of the distribution of these three compounds is included:

Molybdenum. Molybdenum concentrations above the alluvial aquifer background upper tolerance limit (UTL) of 36.3 µg/L have been observed in most of the ER-TCS wells (Figure 3-9). There is no California maximum contaminant level (MCL) for molybdenum. The highest average concentrations of 138 µg/L and 129 µg/L were respectively found in shallow bedrock wells MW-70-105, located in the bottom of East Ravine east of the TCS and MW-74-240, located on the hill near the water tanks south of the TCS. The highest average concentration observed in any of the ER-TCS alluvial wells was 75.4 µg/L at well MW-67-260, located near the north gate of the compressor station. The lowest average molybdenum concentration in the alluvial wells beneath the TCS was 11 µg/L in MW-66-165. The higher concentrations were generally found in the deeper alluvial wells; however, there is no apparent pattern to the distribution of molybdenum across the ER-TCS area wells.

Nitrate. Average nitrate concentrations above the UTL of 5.03 mg/L were found in eleven wells, while concentrations above the California MCL of 10 mg/L were found in eight wells on the compressor station, with higher concentrations generally in shallower wells (Figure 3-10). The highest concentrations, 39.1 and 31 mg/L, were present in shallow alluvial wells MW-66-165 and MW-68-180, respectively. The highest concentration in bedrock was in shallow bedrock well MW-69-195 where the maximum concentration was 22.4 mg/L. Other compressor station wells where nitrate was above the MCL included alluvial wells MW-65-160, MW-65-225, MW-67-185 and MW-67-225. Nitrate was below the MCL in all the other ER-TCS wells.

Selenium. Selenium concentrations above the alluvial aquifer background UTL of 10.3 µg/L were present in several ER-TCS wells on the TCS. The California MCL for selenium is 50 µg/L. The highest concentrations (up to 100 µg/L) were in wells MW-67-185 and MW-67-225, located near the north gate of the TCS (Figure 3-11). Average concentrations above alluvial aquifer background were also found in the shallow alluvial wells MW-66-165 and MW-68-180 and the shallow bedrock well MW-69-195. Average selenium concentrations were below alluvial aquifer background in the deeper alluvial and bedrock wells on the TCS and in all the ER-TCS wells in East Ravine. Maximum concentrations exceeded alluvial aquifer background in both the deep and shallow wells in the MW-60 cluster and in the shallower well at the MW-64 cluster. Both of these well clusters are located south of the axis of the East Ravine.

3.5.3 Sample Results for Additional Constituents

In addition to the constituents listed above, the select ER-TCS wells were sampled for a relatively long list of constituents as defined in the Work Plan Addendum, including Title 22 metals, volatile and semi-volatile organics, PCBs, dioxins/furans, pesticides, PAHs, and fuel hydrocarbons. Highlights of these results include the following:

Inorganics. Compounds present at concentrations above the respective alluvial aquifer background UTL values included arsenic, barium, cobalt, copper, fluoride, mercury, silver, and thallium. As requested by the agencies, detailed evaluation of the occurrence of arsenic and fluoride in the ER-TCS area is provided.

- There were five wells where maximum arsenic concentrations were above the alluvial aquifer UTL of 24.3 µg/L (Figure 3-12)These wells included MW-23-60, MW-62-110, MW-62-190 and MW-57-185 located near the downstream end of the East Ravine, and well MW-74-240 located near the water tanks above the compressor station (Figure 3-12). These are all bedrock wells. Average arsenic concentrations were below the alluvial aquifer UTL in all wells. The highest average concentration was 20.4 µg/L in MW-74-240. There is no apparent pattern of higher concentration in deep or shallow wells. Overall, arsenic concentrations appear to be slightly higher in wells near the river than in wells at the compressor station.
- Fluoride above the UTL of 7.12 µg/L was present in six wells at a maximum concentration of 13 µg/L in well MW-68BR-280 (Figure 3-13). Average fluoride concentrations were above UTL at two locations, MW-67-260, located near the north gate of the compressor station and MW-64BR-LWR, located in the southeast portion of the East Ravine investigation area. Fluoride at average concentrations above the California MCL of 2 µg/L was relatively widespread, occurring in 16 wells. There is no apparent pattern of fluoride distribution with depth or location across the ER-TCS investigation area.

Organics. Organic compounds are not prevalent in ER-TCS area groundwater. The following is a summary of laboratory results for organic compounds.

- Volatile and semi-volatile organics were generally not detected except for low concentrations of acetone, chloromethane, naphthalene, and benzoic acid in well MW-66BR-270, and chloroform in four wells on the TCS.
- PCB compounds were not detected in any of the samples.
- Dioxins were present in seven wells at a maximum concentration of 18 picograms per liter (pg/L), which is the human toxic equivalency); however, of the five wells where follow-up samples were collected, four were nondetect and one had at a decreased concentration of 1.2 pg/L (human toxic equivalency). The MCL for dioxin is 30 pg/L.
- The only pesticides detected were beta- and delta-BHC in the initial sample from MW-65-160; however, these analytes were not detected in the follow-up sample collected from this well.
- The only herbicide detected was meta-chlorophenylpiperazine (MCPP) in the initial sample from MW-67-185 and MW-60BR-245; however, this analyte was not detected in the follow-up samples collected from these wells.
- The only PAH compounds detected were naphthalene and 2-methylnaphthalene in MW-72-80; however, these analytes were not detected in the follow-up sample collected from this well.
- Fuel hydrocarbons were detected in four bedrock wells, with the maximum concentration being 580 µg/L in well MW-74-240.

3.5.4 Stable Isotope Evaluation

In the *Final RCRA Facility Investigation/Remedial Investigation Report* (Final RFI/RI Report); CH2M HILL, 2009b), stable isotopes of oxygen and hydrogen were used to generally identify three water groups: (1) river water and river-influenced groundwater, (2) local alluvial groundwater, and (3) industrial water from historical facility discharges. The groups are intermixed to varying degrees. Figure 3-14 shows the Phase 1 and 2 wells plotted along with offsite alluvial and fluvial non-plume wells. The ovals defining the three water groups on this figure were

developed from an analysis of all the wells at the site at the time of the Final RFI/RI Report. Although there is some overlap between bedrock and alluvial ER-TCS area wells, most of the bedrock wells show a lighter isotopic signature than the alluvial wells. There are two apparent outliers among the bedrock wells. Well MW-63-65 has a significantly lighter signature than other bedrock wells, similar to the river and the offsite fluvial wells. MW-63-65 is located approximately 100 feet from the river. Bedrock well MW-69-195 has a significantly heavier isotopic signature than other bedrock wells, and plots near the isotopically heavy end of the ER-TCS area alluvial wells. MW-69-195 has a higher specific capacity than any of the other ER-TCS area bedrock wells and may be in communication with the nearby alluvial aquifer. Isotopic signatures of bedrock wells such as the MW-23 nested wells, MW-70 cluster, MW-57-70, MW-62-110, and MW-72-80 are intermediate between the bedrock and alluvial groups and may reflect mixing of alluvial and bedrock waters.

3.6 Hydraulic Testing and Water Level Monitoring Results

Hydraulic testing during the Phase 2 consisted of a constant rate-pumping test in well MW-70BR-225 (Site H). Additional hydraulic information is provided by rough estimates of specific capacity obtained during development sampling of the wells.

3.6.1 Constant Rate Extraction Testing

The primary purpose of this test was to provide a qualitative evaluation of the area of influence of MW-70BR-225, which has an open borehole interval that extends from 130 to 227 feet below ground surface. During well development and sampling, it was observed that MW-70BR-225 could sustain a pumping rate of several gallons per minute, which is a significantly higher pumping rate than many other bedrock wells. This test was designed to determine whether the pumping rate could be maintained for an extended period of time and if the drawdown associated with pumping in MW-70BR-225 could be observed in any of the nearby alluvial wells.

MW-70BR-225 was pumped for a period of 12 hours on January 15, 2012. The pumping rate averaged 9.3 gpm and the drawdown recorded was approximately 34 feet. Water levels were monitored with transducers in approximately 20 surrounding wells. The drawdown caused by pumping was too small to observe directly in any but the closest well, MW-70-105 (shallower well pair to the pumping well), where the well exhibited a consistent dewatering trend and a total of 1.6 feet of drawdown during the period of pumping. At other surrounding wells, the water level fluctuations caused by daily changes in river level masked the drawdown caused by pumping. Mathematical deconvolution of the transducer data was necessary to evaluate whether pumping-related drawdown could be observed. Deconvolution was applied to data from seven of the wells closest to the pumping well. Pumping-related drawdown of approximately 0.18 feet was observed at bedrock well MW-58BR, located approximately 300 feet to the east. Pumping-related drawdown was observed but the amount was too small to be accurately quantified in two other bedrock wells, MW-60BR-245 located about 600 feet to the east and MW-69-195 located about 700 feet to the southwest. No pumping-related drawdown was observed in the alluvial wells at MW-59 or MW-68, which are located about 420 feet to the northeast and 450 feet to the northwest, respectively. Figure 3-15 shows the locations of these wells and the drawdown or absence of quantifiable drawdown at each well. Attachment D provides drawdown curves for the pumping well and MW-70-105 and summary graphs of deconvolution analysis.

The nearest alluvial well to MW-70BR-225 is MW-59-100, which is nearly 500 feet away. With the relatively small pumping rate at MW-70BR-225, drawdown would not be expected to be observable in the alluvial aquifer at a radius of 500 feet, and in fact, no drawdown was observed at MW-59-100. Thus, the hydraulic data from the pumping test are considered inconclusive with regard to the possible connection between MW-70BR-225 and the alluvial aquifer, however the relatively high flow rate, the elevated chromium concentration, and the stable isotope signature showing a mixture of bedrock and alluvial water at MW-70BR-225 are all consistent with the theory that this well may be drawing water from the alluvium through a bedrock fracture system.

Groundwater samples were collected from the pump effluent at the beginning, during, and at the end of the MW-70BR-225 test. Analysis of these samples indicated stable Cr(VI) concentrations throughout the test with concentrations ranging from 2,000 to 2,300 µg/L. Measurements of key water quality parameters including pH (7.41), specific conductance (13,030 µS/cm), and ORP (60 millivolts), also remained stable throughout the test.

3.6.2 Specific Capacity Estimates

Specific capacity (the ratio of pumping rate to drawdown) provides a qualitative means of comparing the productivity rate of the different wells. This is considered a rough estimate of well productivity because the pumping rate during sampling is not always held steady and in the more productive wells, the rate and duration of sampling pumping may not be sufficient to stress the well enough to provide a good measurement. Attachment B-2 includes a table summarizing the specific capacity measurements from the various sampling events that occurred at the Phase 2 wells through May 2012, and a figure summarizing available specific capacity data from the ER-TCS area (Figure B2-1). There is often considerable variability between different sampling events in the same well, so these data are considered qualitative. The higher specific capacity (typically greater than 3 gpm per foot [gpm/ft]) is typically observed in the alluvial wells. Several of the bedrock wells pump dry, precluding measurement of specific capacity. The bedrock well with the highest specific capacity (averaging about 2.8 gpm/ft) is MW-69-195, located on the TCS. MW-69-195 is a shallow zone well with 20 feet of screen just below the water table in bedrock. The second-highest bedrock specific capacity (averaging about 0.6 gpm/ft) was observed at well MW-70BR-225, where the constant rate pumping test was conducted. The stable isotope plot (Figure 3-14 shows the isotopic signature of MW-69-195 to be similar to the Phase 2 alluvial wells. MW-70BR-225 appears to be a blend of alluvial and bedrock water types.

3.6.3 Groundwater Gradients

With the installation of the Phase 2 wells, additional monitoring points are available to measure groundwater levels and gradients in the study area. The Phase 1 wells drilled in East Ravine area generally showed that gradients were upward from the bedrock to the alluvium and northward or northeastward from East Ravine area bedrock toward the alluvial aquifer or the river. Figure 3-16 shows the water levels measured on January 15, 2012. Wells are color-coded according to unconsolidated aquifer zone as determined by the elevation monitored. Bedrock wells are identified by a separate color (green). The inset on this figure shows the vertical gradients at seven locations. These gradients are all upward. Figure 3-17 shows contoured groundwater levels in the shallow bedrock and alluvial wells. The contours show groundwater gradients generally to the northeast along the axis of East Ravine and to the north from the TCS. In fractured bedrock, groundwater tends to follow conductive fractures so that the direction of groundwater movement might not be directly down-gradient.

3.7 Data Quality Evaluation Summary

A data quality evaluation (DQE) was conducted to assess the data quality of analytical results included in this technical memorandum. The complete DQE is provided as Attachment E-1 and E-2 for soil and groundwater data, respectively.

3.7.1 Soil Data Quality Evaluation Summary

The following summary highlights the soil DQE findings:

1. The completeness objective for the PG&E program is 90% for soil samples. The completeness objectives were met for all method/analyte combinations with the exception of 1,1´-Biphenyl (SW8270C). Although found in natural gas and used as a precursor for the production of PCBs this compound is difficult to analyze and is unlikely to be found in any significant amounts at the Topock Compressor Station. Although all of the 1,1´-Biphenyl results were non-detect, only 36.8% of the 1,1´-Biphenyl results met the completeness objectives.
2. Samples were collected and analyzed based on approved methods/procedures and the results are reported using industry-standardized units.
3. The routinely acceptable performance of field and laboratory QC indicators (field duplicates [FDs], field blanks, laboratory blanks, laboratory control samples [LCS], matrix spike/matrix spike duplicate [MS/MSD], surrogate, and calibrations) generally show the accuracy and precision of the data meet the project objectives.
    - Eight dioxin samples (SW8290) had results that were qualified as not detected due to method blank contamination.

- 2,2-Dichloropropane results from nineteen volatiles samples (SW8260) were qualified as estimated values due to calibration criteria exceedances.
- One PCB (SW8082) and one dioxin (SW8290) sample were qualified due to surrogate recovery outside the method criteria.
- Six metals samples (SW6010B/SW6020A), four semi-volatile samples (SW8270C), one Cyanide sample (SW9014), nine TOCs samples (SW9060), and one TPH Motor Oil (SW8015B) sample were qualified as estimated values due to matrix spike exceedances.
- Eight FD pairs for metals (SW6010B) and six FD pairs for TOC (SW9060) exceeded the relative percent difference (RPD) criteria.
- The semi-volatile (SW8270C) samples discussed above, had no recovery of 1,1´-Biphenyl in the LCS; the 1,1´-Biphenyl results of 12 samples were rejected.
- Seven semi-volatile samples (SW8270C) had five compounds (1,1´-Biphenyl, Benzaldehyde, Acetophenone, Hexachlorocyclopentadiene, and 1,2,4,5-Tetrachlorobenzene) qualified as estimated due to LCS recovery exceedances. All five compounds are compounds that are not part of the laboratory's normal reporting list of compounds.

4. Results from six cyanide (SW9014) samples were qualified as estimated due to holding time exceedance.
5. Analytical data as qualified meet the data quality objectives and may be used in project decision making with the exception of 1,1´-Biphenyl (SW8270C).

3.7.2 Groundwater Data Quality Evaluation Summary

The following summary highlights the groundwater DQE findings:

1. The completeness objective for the PG&E program is 95 percent (%) for groundwater samples. The completeness objective was met for all method/analyte combinations.
2. Samples were collected and analyzed based on approved methods/procedures and the results are reported using industry-standardized units.
3. The routinely acceptable performance of field and laboratory QC indicators (FDs, field blanks, laboratory blanks, LCS, MS/MSD, surrogate, and calibrations) generally show the accuracy and precision of the data meet the project objectives.
    - One chromium (SW6020A) and three toluene (SW8260) results were qualified as not detected due to equipment blank (EB) contamination.
    - Thirty three samples were associated with negative laboratory blanks that exceeded the absolute value of the RL for one or more metals (SW6010B - aluminum, beryllium, cobalt, iron, nickel, and silver).
    - Three dioxin samples (SW8290) and two semi-volatile samples (SW8270C) had results that were qualified as not detected due to method blank contamination.
    - Two samples analyzed for magnesium and nickel (SW6010B) were qualified due to calibration blank contamination.
    - One Cr(VI) sample (EPA218.6), two metals samples (SW6010B), three herbicides samples (SW8151), nine semi-volatile samples (SW8270C), 15 volatile samples (SW8260B), and four dioxin samples (SW8290) were qualified as estimated values due to calibration exceedances.
    - One herbicide sample (SW8151), one semi-volatile sample (SW8270C), Two TPH-Diesel/TPH-Motor Oil samples (SW8015B), and two PCB samples (SW8082) were qualified due to surrogate recovery outside the method criteria.

- Two dioxin (SW8290) samples were qualified due to internal standard recovery outside the method criteria.
- One TPH-Diesel sample (SW8015B), One TPH-Gasoline sample (SW8015B), eight volatiles samples (SW8260B), Twenty one metals samples (SW6010B/SW6020A), and twelve orthophosphate samples (EPA300.0) were qualified as estimated values due to MS/MSD exceedances.
- One FD pair for Nitrate (E300.0), one FD pair for Ammonia (SM4500N H3 C), two FD pairs for Alkalinity (SM2320 B), and three FD pairs for Iron (SW6010B) exceeded the RPD criteria.
- Twenty one carbonate alkalinity samples (SM2320B), two herbicides samples (SW8151), three semi-volatile samples (SW8270C), two PAH samples (SW8270SIM), and three dioxin samples (SW8290) were qualified as estimated values due to LCS recovery exceedances.

4. Two herbicide samples (SW8151) and two semi-volatile samples (SW8270C) were extracted outside the EPA recommended holding time.
5. Matrix effects were identified in eight samples for Cr(VI) (E218.6) analyses and the RLs were raised to the concentrations where the matrix effects were overcome as indicated by acceptable MS analyses

4.0 Refinements to the Topock Conceptual Site Model

Analysis of the data collected during the installation, sampling, and testing of ER-TCS investigation wells has not resulted in any major revisions to the conceptual site model. The distribution of chromium and other COPCs has been better defined by the ER-TCS wells. The nitrate concentrations in the recently installed alluvial wells beneath the TCS are generally higher than in other wells at the site. DTSC comment notes that the nitrate distribution may suggest the station is/was a source. Lithologic data collected during the installation of these wells provide better definition of the topography of the bedrock contact below the TCS and, as a result, indicate a larger area of saturated alluvium beneath the TCS than previously estimated. The highest concentrations of Cr(VI) yet detected at the site are observed in the saturated alluvium beneath the TCS within an area of elevated concentrations in the parts per million on the north and east sides of the TCS. Although these concentrations are not unlike concentrations previously observed to the north and northeast of the TCS, it does appear that the area of elevated concentrations around the compressor station is larger than previously understood during the 30% design. This finding has been taken into account in the subsequent phases of the design by adding two carbon-amended injection wells (TCS-1 and TCS-2) to accelerate remediation of Cr(VI) in the alluvium under the TCS. Based on the data from MW-66BR-270 and MW-68BR-280, concentrations of Cr(VI) in the alluvium do not extend into the bedrock directly beneath the TCS. Concentrations of Cr(VI) are observed in bedrock well MW-69-195 immediately south of the TCS fence line where saturated alluvium is not present, but Cr(VI) has not been detected in the southern most bedrock well MW-74-240.

The extent of Cr(VI) contamination in the East Ravine area has been further defined both laterally and vertically. With the exception of concentrations detected in the parts per million at MW-70BR-225, Cr(VI) concentrations observed in the new wells are similar to the previously installed wells and do not suggest any previously unknown hotspots or contaminant sources outside the compressor station, which was always considered a potential source location. As discussed above, MW-70BR-225 and the well immediately south of the TCS fence line (MW-69-195) exhibit higher specific capacity than previous bedrock wells. These two higher-producing bedrock wells, which are located relatively close to the inferred contact of the alluvial aquifer and bedrock, also exhibit water quality similar to the alluvial aquifer. The data collected suggest a localized fracture connection to the alluvium rather than to some as yet undiscovered zone of highly fractured and more permeable bedrock.

The distribution of conductive fractures can be inferred from the hydrophysical logging. The hydrophysical logs typically indicate a few (zero to four) zones of discrete flow within an interval of open borehole ranging from 90 to 150 feet in length. Often, one of these zones was dominant and others were relatively minor. The conceptual model suggested by the hydrophysical logging is that groundwater flow occurs in relatively widely spaced discrete fractures. Based on the flow characterization conducted in the boreholes, the bulk rock matrix and many of the fractures do not transmit water, which is a flow regime that is typical in crystalline bedrock systems. The locations

of inflow to the boreholes are generally not correlated with highly fractured zones or zones of poor quality rock (based on rock core recovered) but rather with discrete fractures in relatively competent rock. [2]

Based on the widespread distribution of Cr(VI) in East Ravine bedrock, the discrete fractures observed in the boreholes may form an interconnected network. Constituents can travel relatively quickly through networks of interconnected fractures. Compared to a porous media aquifer where water occupies all the spaces between the grains in the porous matrix, a relatively small amount of water is required to fill a sparse fracture network in a block of low porosity bedrock. The chromium distribution in East Ravine bedrock likely resulted from Cr(VI) in water that ponded in the East Ravine. The ponded water could have infiltrated through the alluvium beneath the ponds and into fractures in the underlying bedrock. The head in the ponds would have been 60 to 80 feet higher than the head in the fractures, so the infiltrating water would have sufficient driving force to displace the water in the fractures, allowing Cr(VI) to enter the fracture network. Because the volume of the water in the fracture network is small, a relatively short period of ponding could have provided a sufficient volume of water to displace the groundwater in a network of bedrock fractures. Because of the sparse nature of the fractures, the volume of the Cr(VI) plume in bedrock likely represent less than 2% of the total volume in the plume.

The groundwater model for the Topock has been modified to more accurately represent the transport in the fractured rock. The current model treats the fractured bedrock the same as the alluvial aquifer but with lower permeability. In reality, groundwater flow through the bedrock occurs through a network of discrete fractures. However the obtaining the data necessary to define the complex geometry of the interconnecting fracture network would require the installation of many additional boreholes and combined with extensive hydraulic and tracer testing. Due to the impracticality of defining and simulating the fracture network, the modeling approach will simulate the fractured rock portion of the model as a porous media with very small mobile porosity. The Topock transport model is set up to simulate dual-porosity. The mobile porosity represents the connected pores or fractures that transmit water. The immobile porosity simulates the dead end pores or blocked fractures that are saturated and may provide a reservoir of contaminant mass but do not readily transmit water. Currently, the mobile porosity in the Topock model is set to 12% and the immobile is 23%, adding up to a total porosity of 35%. These are typical values for an alluvial aquifer but are not considered reasonable for fractured rock. In fractured crystalline rock, typical mobile porosity (representing the fracture network) is 1% or less.

The approach of using a dual porosity model to simulate fractured rock is based on the fact that at a large enough scale, many fractured rock flow systems can be effectively simulated as porous media with low mobile porosity. As a general rule of thumb, the size of the block of fractured rock that may be treated as a porous media is often considered to be about 100 times the average fracture spacing (Gerber, Bither, and Muff, 1991). An analysis of the rock core logs from the Phase 1 and 2 ER-TCS area boreholes (see boring logs in Attachment A-2) shows average fracture spacing in the saturated zone to be about 0.29 feet. The transport model grid cells in the East Ravine / TCS area are 25 feet square. The current model grid spacing is therefore close to the 100 times the fracture spacing, suggesting that it is not unreasonable to use the existing model to simulate the fractured rock at Topock. Measurements of drawdown and pumping rate collected during purging prior to sampling can be used to estimate specific capacity, which then can be used to infer the relative hydraulic conductivity of the bedrock at different locations. The relatively wide range in specific capacity suggests a similarly wide range in hydraulic conductivity, which is typical of wells in fractured crystalline bedrock. At the higher end, the average specific capacity in bedrock wells MW-70BR-225 and MW-69-195 appears to be between 2 and 3 gpm/ft; the lower end of the specific capacity range is 0.01 gpm/ft or less. Several of the bedrock wells pump dry such that specific capacity cannot be accurately measured. Pumping from the bedrock during the MW-70BR-225 constant rate test did not induce discernible drawdown in the nearest wells completed in the alluvial aquifer, but this is not surprising given the distance to the nearest alluvial monitor wells and the relatively low pumping rate considering the relatively large storage of the alluvial aquifer. Overall, the metadiorite bedrock exhibits relatively low specific capacity indicating similarly low hydraulic conductivity in comparison with the alluvial aquifer.

[2] This and the next paragraph regarding conductive fractures were included to speak more directly to the comment DOI-18 on the Preliminary (30 percent) Design Submittal for the Final Groundwater Remedy (CH2M HILL, 2011).

Data collected as part of the ER-TCS confirm the hydrogeologic setting for the conceptual site model. Groundwater in the bedrock occurs in irregularly distributed, highly localized, and discontinuous water-bearing zones that is characteristic of fractured crystalline rocks. This refined conceptual site model confirms previously available data, therefore assumptions associated with the anticipated design and operation of the final groundwater remedy do not need to be modified.

Based on discussions held with the agencies and stakeholders during implementation, investigation activities included in the Work Plan Addendum are complete with the exception of Site H (MW-70 well series). The agencies have directed PG&E to conduct additional characterization to determine the vertical extent of Cr(VI) in groundwater at Site H. As discussed with the agencies, this work will be coordinated with the remedial design and conducted as part of the implementation of the groundwater remedy.

Notes:

Monitoring zones:

PA = Perched Alluvial Aquifer

UA = Unconsolidated Alluvial Aquifer

BR = bedrock formations: including Miocene Conglomerate (Tmc) and pre-Tertiary metadiorite bedrock (pTbr).

bgs = below ground surface

MSL = Mean Sea Level

TABLE 3-1

Summary of Lithology Encountered During the ER-TCS Groundwater Investigation

Revised Addendum to the Summary of Findings Associated with the East Ravine Groundwater Investigation

Pacific Gas and Electric Company, Topock Compressor Station, Needles, California

Site ID	Monitoring Wells Completed	Approximate Depth to Groundwater (ft bgs)	Total Boring Depth (ft bgs)	Start Depth (ft bgs)	End Depth (ft bgs)	Summary of Lithologic Description
A	MW-58-065 MW-58-115 MW-58-205	66	206	0	60	**Unconsolidated alluvium:** silt with sand and silty gravel, silty sand with gravel, and poorly graded sand with gravel.
				60	65.5	Highly weathered **metadiorite bedrock** becoming more competent toward the bottom of the interval.
				65.5	206	Competent pre-tertiary **metadiorite bedrock** (metadiorite);dusky yellowish green with intermediate (dioritic) mineralogy, and a medium grained, strong, unweathered, and massive to foliated rock mass.
B	MW-57-050 MW-57-070 MW-57-185	52	192	0	46	**Unconsolidated alluvium:** sandy silt with gravel and silty gravel.
				46	144.5	Competent Miocene **conglomerate bedrock** (conglomerate); yellowish red, fine- to coarse-grained, medium strong, unweathered, matrix supported and massive.
				144.5	153	Completely weathered **conglomerate bedrock** similar to that from 46 to 144.5 feet bgs, but cement has been largely replaced or removed. The conglomerate is medium strong; however, the matrix rapidly dissolved when exposed to water.
				153	154.5	**Metaconglomerate:** dark yellowish-orange, strong, and unweathered. The matrix composed of moderate reaction to hydrochloric acid (HCl) solution minerals; however, the relict conglomerate structure was still apparent.
				154.5	155.5	**Altered metadiorite bedrock:** yellowish-brown with largely felsic mineralogy; medium-grained, strong, and unweathered. No reaction to HCl solution. Portions of this interval exhibited a mylonitic texture, inferred to be associated with displacement along a portion of the Chemehuevi detachment fault.
				155.5	192	**Metadiorite bedrock:** dusky yellowish-green, with an intermediate (dioritic) mineralogy and fine- to medium-grained, strong, unweathered, and massive to foliated rock mass.
C	MW-61-110	87	112.5	0	63	**Unconsolidated alluvium:** poorly graded silty sand with gravel and poorly graded sand with silt and gravel.
				63	112.5	**Metadiorite bedrock:** dusky yellowish-green, hard to very hard, with intermediate (dioritic) mineralogy and fine-grained, unweathered, and massive to foliated rock mass.
C-Alt	MW-64-150 MW-64-205 MW-64-260	120	260.5	0	260.5	**Metadiorite bedrock**; grayish olive, intermediate (dioritic) mineralogy, with a strong, unweathered to slightly weathered, massive to foliated rock mass.
E	MW-62-065 MW-62-110 MW-62-190	47	191.5	0	4.5	**Unconsolidated alluvium:** silty sand.
				4.5	191.5	**Conglomerate bedrock:** reddish-brown, strong, unweathered, and massive, with a fine-grained matrix and coarse sand to gravel-sized clasts of no dominant mineralogy.
E-Alt2	MW-63-065	49	66	49	66	**Conglomerate bedrock** was observed from ground surface. Bedrock moderate brown, matrix supported, and friable, with a moderately to completely weathered rock mass and clasts as large as 4 centimeters.
F	MW-60-125* MW-60BR-245	98	200	0	9	**Unconsolidated alluvium:** dark yellowish-brown silty sand.
				9	200	**Metadiorite bedrock:** grayish-green to dusky green with intermediate (dioritic) mineralogy with a medium-grained, unweathered, and massive to foliated rock mass.
G	MW-59-100	84	101	0	82	**Unconsolidated alluvium:** brown to yellowish-brown silty sand.
				82	101	**Unconsolidated alluvium:** dark grayish-brown and dark reddish-brown gravelly sand with appearance of completely weather conglomerate bedrock.
MW-23	MW-23-060 MW-23-080	48	80	NA	NA	**Conglomerate bedrock**.
H	MW-70-105 MW-70-225	84	227	0	69	**Unconsolidated alluvium:** light yellowish-brown silty sand.
				69	227	**Metadiorite bedrock:** dusky yellow green with intermediate (dioritic) mineralogy with a medium-grained, unweathered, and massive to non-foliated rock mass.
I	MW-73-80	52	123	0	7	**Unconsolidated alluvium:** brown silty sand.
				7	81	**Metadiorite bedrock:** dusky yellow green with phaneritic mineralogy with a medium-grained, unweathered, highly fractured, and massive to non-foliated rock mass.
J	MW-74-240	216	240	0	240	**Metadiorite bedrock:** dusky yellow green with intermediate (dioritic) mineralogy with a medium-grained, unweathered, and massive to non-foliated rock mass.
K	MW-72-080 MW-72BR-200	59	200	0	13	**Unconsolidated alluvium:** light brownish gray silty sand with gravel.
				13	200	**Metadiorite bedrock:** dusky yellow green with phaneritic mineralogy with a medium-grained, slightly weathered, fractured, and massive to non-foliated rock mass.
L	MW-71-35	8	71	0	35	**Unconsolidated alluvium:** brown silty sand.
				35	71	**Conglomerate bedrock:** dark reddish-brown, strong, slightly weathered, and massive, with a fine-grained matrix and coarse sand to gravel-sized clasts of no dominant mineralogy.
2	MW-67-185 MW-67-225 MW-67-260	171	272.5	0	264	**Unconsolidated alluvium:** sand from 0'-53', clay from 53'-73', silt from 73'-92', gravel from 92'-197', silt from 197'-211', sand from 211'-221', silt from 221'-264'.
				264	271	**Conglomerate bedrock:** dark reddish-brown, strong, slightly weathered, and massive, with a fine-grained matrix and coarse sand to gravel-sized clasts of no dominant mineralogy.
				271	272.5	**Metadiorite bedrock:** dusky yellowish-green with phaneritic mineralogy with a medium-grained, slightly weathered, fractured, and massive to non-foliated rock mass.
3	MW-68-180 MW-68-240 MW-68BR-280	166	280.5	0	243	**Unconsolidated alluvium:** sand from 0'-62', gravel from 62'-243'
				243	258	**Conglomerate bedrock:** dark reddish-brown, massive, with a fine-grained matrix and coarse sand to gravel-sized clasts of no dominant mineralogy.
				258	280.5	**Metadiorite bedrock:** pale yellowish-brown with phaneritic mineralogy with a medium-grained, weathered, and massive to non-foliated rock mass.
4	MW-69-195	176	227	0	42	**Unconsolidated alluvium:** light yellowish-brown gravel.
				42	197.5	**Metadiorite bedrock:** dusky yellowish-green with phaneritic mineralogy with a medium-grained, slightly weathered, fractured, and massive to non-foliated rock mass.
5	MW-65-160 MW-65-225	141	237	0	228	**Unconsolidated alluvium:** sand from 0'-168', gravel from 168'-228'
				228	237	**Metadiorite bedrock:** dusky yellowish-green with phaneritic mineralogy with a medium-grained, slightly weathered, fractured, and massive to non-foliated rock mass.
6	MW-66-165 MW-66-230 MW-66BR-270	131	237	0	233	**Unconsolidated alluvium:** sand from 0'-19', silt from 19'-32', from 32'-132', gravel from 132'-157', sand from 157'-162.5', gravel from 162.5'-233'.
				233	271	**Conglomerate bedrock:** dark reddish-brown, massive, with a fine-grained matrix and coarse sand to gravel-sized clasts of no dominant mineralogy, highly cemented.

TABLE 3-2

Groundwater Analytical Results for ER-TCS Area Groundwater Investigation Monitoring Wells, Hexavalent Chromium and Selected Dissolved Metals

Revised Addendum to the Summary of Findings Associated with the East Ravine Groundwater Investigation

PG&E Topock Compressor Station Needles, California

Notes:

-- = not analyzed

FD = field duplicate

J = concentration estimated by laboratory or data validation

ND = not detected at listed reporting limit

R' = Due to the influence of well construction materials, the results were shown to not be representative of aquifer conditions and were considered to be unusable and

µg/L = micrograms per liter

Notes:

When calculating averages, zero was used for non-detect results.

* Monitoring wells MW-58BR and MW-64BR have used multiple monitoring configurations throughout the East Ravine investigation (see well construction information).

Average, minimum, and maximum values shown are for the most recent, depth-specific monitoring well configuration, which is the most comprehensive data set of all past monitoring configurations.

See Table 3-2 for results from other configurations.

-- = not analyzed

J = concentration estimated by laboratory or data validation

ND = not detected at listed reporting limit

µg/L = micrograms per liter

Notes:

When calculating averages, zero was used for non-detect results.

* Monitoring wells MW-58BR and MW-64BR have used multiple monitoring configurations throughout the East Ravine investigation (see well construction information).

Average, minimum, and maximum values shown are for the most recent, depth-specific monitoring well configuration, which is the most comprehensive data set of all past monitoring configurations.

See Table 3-4 for results from other configurations.

-- = not analyzed

0/00 = differences from global standard in parts per thousand

J = concentration estimated by laboratory or data validation

mg/L = milligrams per liter

ND = not detected at listed reporting limit

TABLE 3-6

Groundwater Analytical Results for ER-TCS Area Groundwater Investigation Monitoring Wells, Field Water Quality Parameters

Revised Addendum to the Summary of Findings Associated with the East Ravine Groundwater Investigation

PG&E Topock Compressor Station Needles, California

Location	Sample Date	Field Data						
		Specific Conductance (µS/cm)	Temperature (°C)	pH (pH units)	ORP (mV)	Dissolved Oxygen (mg/L)	Salinity (%)	Turbidity (NTU)
MW-74-240	20-Dec-12	850	24.2	8.96	-12	0.15	0.055	40.0
	01-Mar-13	1,050	25.7	9.06	-41	0.28	0.068	13.0

Notes:

-- = not analyzed

°C = degree centigrade

% = percentage

FD = field duplicate

mg/L = milligrams per liter

mV = millivolts

ND = not detected at listed reporting limit

NTU = Nephelometric Turbidity Unit

ORP = oxidation reduction potential, results rounded off to whole point

µS/cm = microSiemens per centimeter

Notes:

When calculating averages, zero was used for non-detect results.

* Monitoring wells MW-58BR and MW-64BR have used multiple monitoring configurations throughout the East Ravine investigation (see well construction information).

Average, minimum, and maximum values shown are for the most recent, depth-specific monitoring well configuration, which is the most comprehensive data set of all past monitoring configurations.

See Table 3-6 for results from other configurations.

-- = not analyzed

°C = degree centigrade

% = percentage

mg/L = milligrams per liter

mV = millivolts

ND = not detected at listed reporting limit

NTU = Nephelometric Turbidity Unit

ORP = oxidation reduction potential, results rounded off to whole point

µS/cm = microSiemens per centimeter

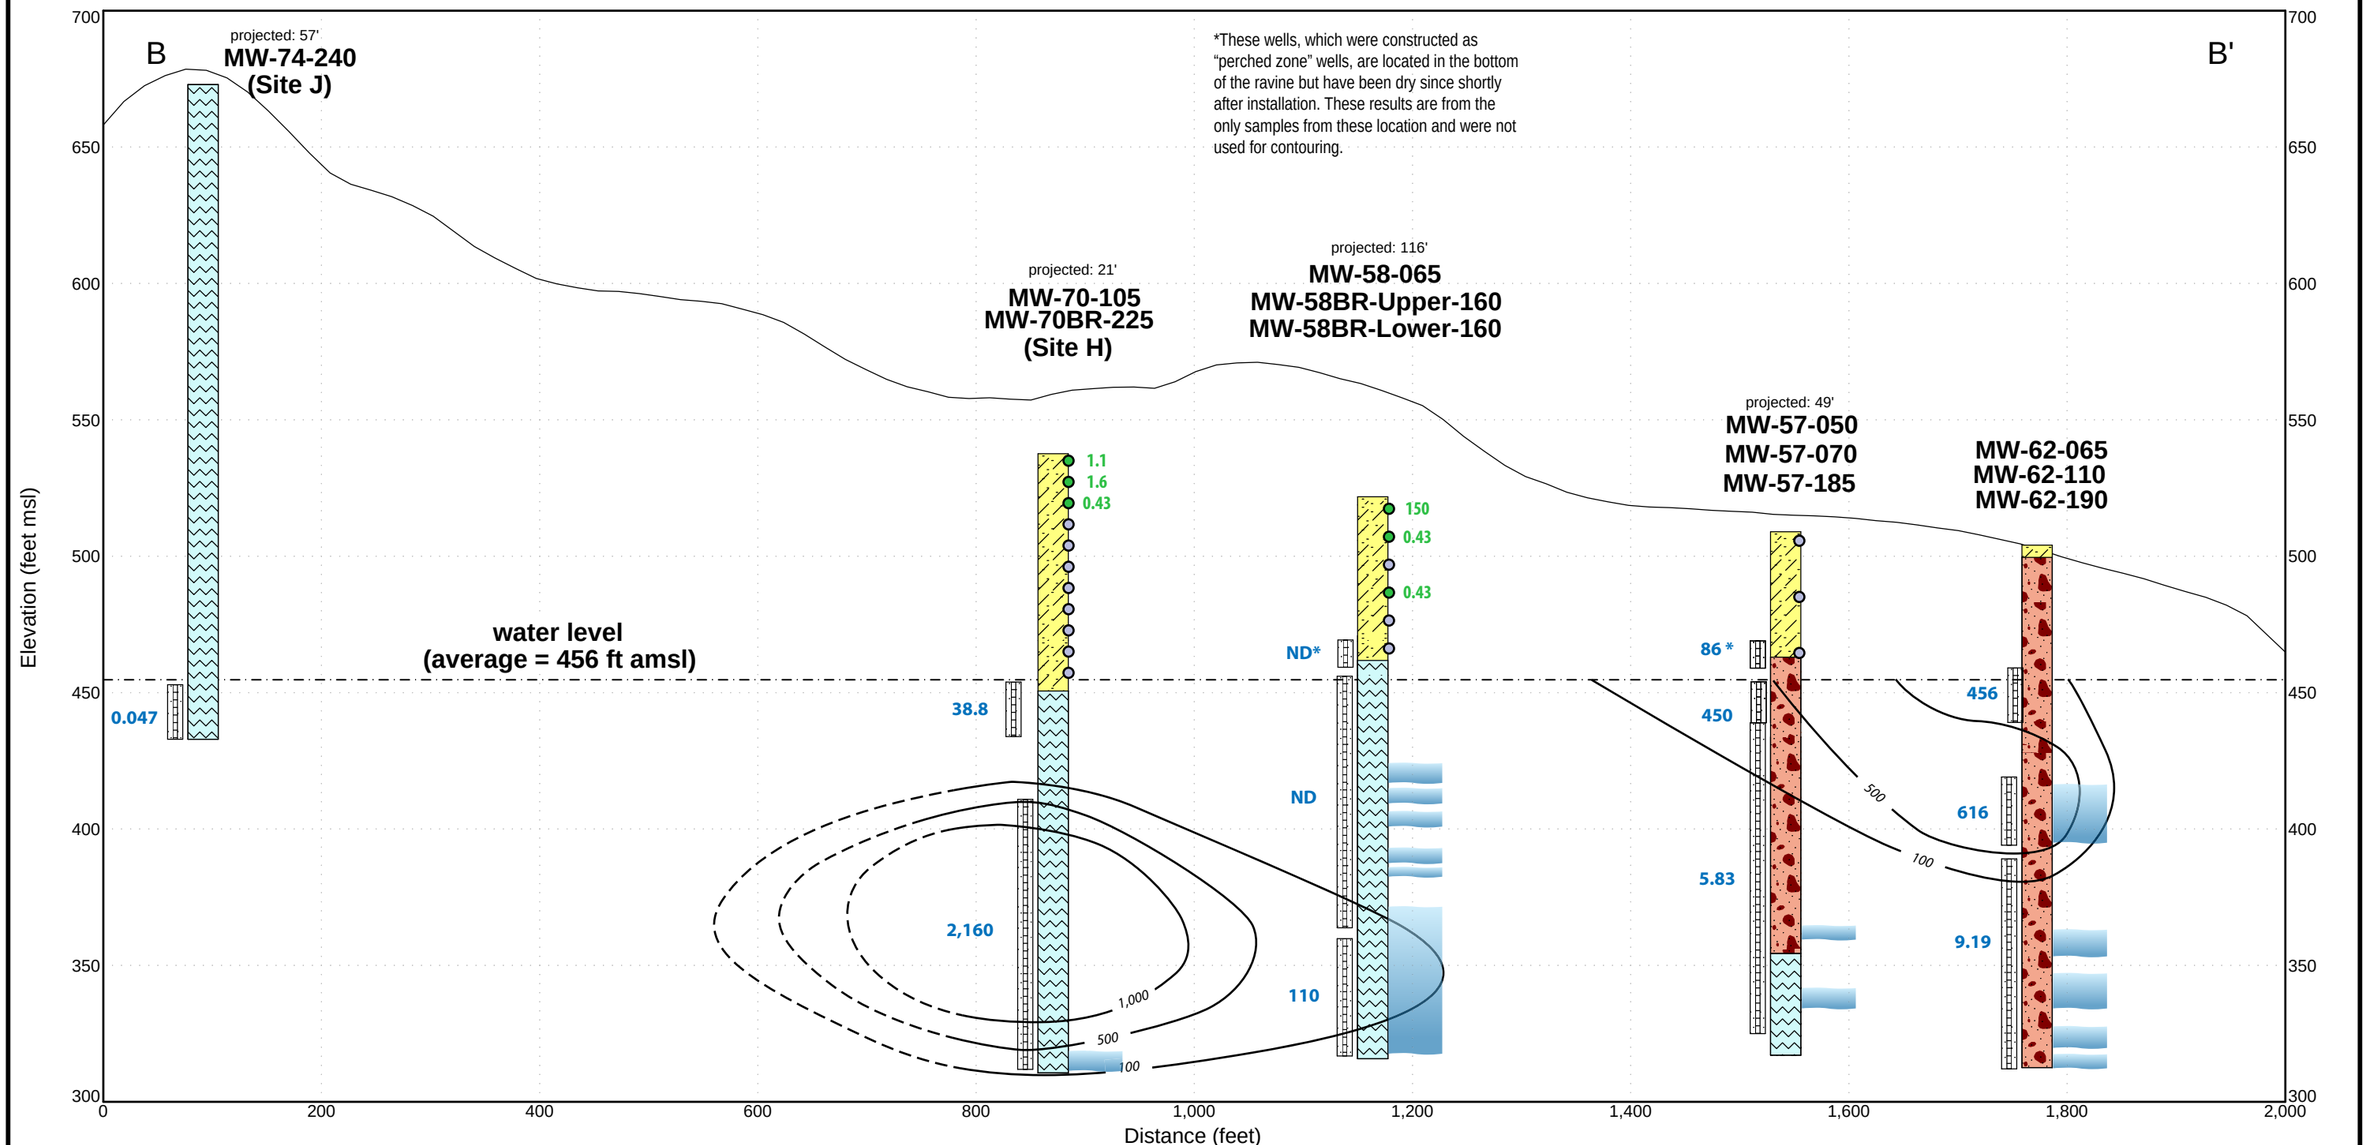
ND – Not Detected
ug/L – micrograms per liter
mg/kg – milligrams per kilogram
ft amsl – feet above mean sea level

Notes:
1. Inferred isoconcentration lines are provided at agency request to assist with conceptual data interpretation. These lines are not intended to represent the actual plume distribution for reasons including that concentrations contoured represent calculated average concentrations, do not incorporate any bedrock fracture complexities, and that most wells are projected onto the section.
2. Well clusters shown as single boring
3. Flow zones identified are based on the results of flow profiling within the given borehole. Groundwater flow directions flow within the fractured bedrock cannot be inferred from borehole to borehole given the nature of the fracture network.

LITHOLOGY



- **Alluvium**
- **Miocene Conglomerate**
- **Metadiorite**

NOTES:

1. All water levels are based on measurments collected during the 1/15/2012 "snap-shot" event, except for MW-66BR-270, which is from 9/22/2011.
2. Colors related to geologic type are explained in the map legend.

LEGEND

- Monitoring Well
- Bedrock Well or Borehole
- Approximate Bedrock Contact at 455 ft MSL
- MW-43-025- - - - Location ID
  454.32- - - - Groundwater Elevation (feet MSL)

Groundwater Model Layers

- MW-31-060 = Upper Layer
- MW-67-225 = Middle Layer
- MW-59-100 = Lower Layer

  (Unconsolidated Aquifer)
- MW-61-110 = Bedrock Zone
  Bedrock Layer

Notes:

1. Reported groundwater elevations are based on manual water level and pressure transducer data collected on 1/15/2012, except for MW-66BR-270, which is from 9/22/2011. Due to the very low permeability at MW-66BR-270, the water level in January was still recovering from the previous sampling event.
2. Due to the FLUTe$_{TM}$ sampling equipment installed in well MW-62 water levels could not be measured in MW-62-110 and MW-62-190 during this event.
3. During the "snap-shot" water level event, it was noted that the inflatable packer in MW-58BR had deflated; therefore the water level measured at this well is representative of the groundwater elevation for MW-58BR-LWR, as it is reported.
4. Due to the inflatable packer installed in well MW-64BR, only the water level of the upper zone, MW-64BR-UPR, could be measured during the "snap-shot" event.

Borehole Construction Narrative

Appendix A-1: Borehole Construction Narrative (Phase 1)

The following bullets provide a summary of the drilling activities conducted to facilitate lithologic and hydrogeologic characterization, and well installation at each ERGI investigation site:

- Site A (MW-58 well series) – Two boreholes were advanced at Site A. An initial exploratory borehole was advanced to 115 feet bgs using a combination of rotosonic and rotary core drilling. To facilitate rotary coring and segregate the deeper portion of the borehole, a permanent 6-inch poly vinyl chloride (PVC) conductor casing was installed to 65.5 ft bgs and sealed with Portland cement grout. Subsequent to testing the 115-foot borehole, it was deepened to a final total depth of 206 feet bgs. Based lithologic and hydraulic data collected from the initial borehole, a second borehole was installed to 64 feet bgs for well installation.

- Site B (MW-57 well series) – Three boreholes were advanced at Site B. An initial exploratory borehole was advance to 192 feet bgs using a combination of rotosonic and rotary core drilling. To facilitate rotary coring and segregate the deeper portion of the borehole, a permanent 5-inch PVC conductor casing was installed to 70 feet bgs and sealed with Portland cement grout. Based on lithologic and hydraulic data collected from the initial borehole, two additional boreholes were installed to 50 and 70 feet bgs for well installation.

- Site C (MW-61-110) – One borehole was advanced at Site C to a total depth of 112 feet bgs for well installation. The borehole was initially advanced to 68 feet bgs using rotosonic drilling methods. The rotosonic casing was then used as a temporary conductor casing to facilitate rotary core drilling, which was used to advance the borehole to total depth. The cored borehole was then over-drilled from 68 feet bgs to total depth using rotosonic methods to facilitate well installation.

- Site C-Alternate (MW-64 well series) – One borehole was advanced at Site C-Alternate to a total depth of 260.5 feet bgs. The borehole was initially drilled 20 feet bgs using rotosonic drilling for the installation of a permanent 6-inch PVC conductor casing (sealed with Portland cement grout). Rotary core drilling was then used to advance the borehole to total depth.

- Site D – No borings were installed at Site D.

- Site E (MW-62 well series) – Two boreholes were advanced at Site E. The initial borehole was advanced to a total depth of 75 feet bgs for well installation. This borehole was initially advanced to 21 feet bgs using rotosonic drilling, and then to total depth with rotary core drilling using the rotosonic casing as a temporary conductor casing. The cored borehole was then over-drilled from 21 feet bgs to total depth using rotosonic methods to facilitate well installation. The second borehole was initially advanced to 75 feet bgs using rotosonic drilling for the installation of a permanent 6-inch PVC conductor casing (sealed with Portland cement grout). The boring was then advanced to a total depth of 191.5 feet bgs using rotary core drilling.

- Site E-Alternate 1 (MW-23 re-build) – No borings were installed at Site E-Alternate 1. In lieu of installing a new boring at this location, nearby existing monitoring well MW-23

was re-built to address the objectives of this investigation. MW-23 was over-drilled using rotosonic drilling to facilitate well re-installation within the pre-existing borehole.

- Site E-Alternate 2 (MW-63-065) – One borehole was advanced at Site E-Alternate 2 to a total depth of 66 feet bgs for well installation. The borehole was initially advanced to 30 feet bgs using rotosonic drilling methods. The rotosonic casing was then used as a temporary conductor casing to facilitate rotary core drilling, which was used to advance the borehole to total depth. The cored borehole was then over-drilled from 30 feet bgs to total depth using rotosonic methods to facilitate well installation.
- Site F (MW-60-125) – One borehole was advanced at Site F to a total depth of 123 feet bgs for well installation. The borehole was initially advanced to 86.5 feet bgs using rotosonic drilling methods. The rotosonic casing was then used as a temporary conductor casing to facilitate rotary core drilling, which was used to advance the borehole to total depth. The cored borehole was then over-drilled from 86.5 feet bgs to total depth using rotosonic methods to facilitate well installation.
- Site G (MW-59-100) – One borehole was advanced at Site G to a total depth of 101 feet bgs for well installation. This borehole was installed using only rotosonic drilling.

Appendix A-1: Borehole Construction Narrative (Phase 2)

The following bullets provide a summary of the drilling activities conducted to facilitate lithologic and hydrogeologic characterization, and well installation at each ER-TCS investigation site:

- Site F (MW-60 well series) – Two boreholes were advanced at Site F: the shallow one during the 2009 investigation and the deeper during the 2011 investigation. The initial borehole advanced to 86.5 feet bgs using rotosonic drilling, and then to 123 feet bgs with rotary core drilling using the rotosonic casing as a temporary conductor casing. The cored borehole was then over-drilled from 86.5 feet bgs to total depth using rotosonic methods to facilitate well installation. The second borehole was initially advanced to 137 feet bgs using rotosonic drilling for the installation of a permanent 5-inch PVC conductor casing (sealed with Portland cement grout). The boring was then advanced to a total depth of 245 feet bgs using rotary core drilling.

- Site H (MW-70 well series) – Two boreholes were advanced at Site H. The initial borehole was advanced to 87 feet bgs using rotosonic drilling, and then to 107.8 feet bgs with rotary core drilling using the rotosonic casing as a temporary conductor casing. The cored borehole was then over-drilled from 87 feet bgs to total depth using rotosonic methods to facilitate well installation. The second borehole was initially advanced to 130 feet bgs using rotosonic drilling for the installation of a permanent 5-inch PVC conductor casing (sealed with Portland cement grout). The boring was then advanced to a total depth of 227 feet bgs using rotary core drilling.

- Site I (MW-73-80) - One borehole was advanced at Site I to a total depth of 81 feet bgs. The borehole was advanced to 7 feet bgs using rotosonic drilling, and then to 81 feet bgs with rotary core drilling using the rotosonic casing as a temporary conductor casing. The cored borehole was then over-drilled from 7 feet bgs to total depth using rotosonic methods to facilitate well installation.

- Site J (MW-74-240) - One borehole was advanced at Site J to a total depth of 240 feet bgs for well installation. The borehole was initially advanced to 19 feet bgs using rotosonic drilling methods. The rotosonic casing was then used as a temporary conductor casing to facilitate air hammer and rotary core drilling. Air hammer was used to advance the borehole from 19 to 211 feet using, and rotary core drilling was then used from 211 feet total depth. The borehole was then over-drilled from 19 feet bgs to total depth using rotosonic methods to facilitate well installation.

- Site K (MW-72 well series) – Two boreholes were advanced at Site K. The initial borehole was advanced to 17 feet bgs using rotosonic drilling, and then to 80 feet bgs with rotary core drilling using the rotosonic casing as a temporary conductor casing. The cored borehole was then over-drilled from 17 feet bgs to total depth using rotosonic methods to facilitate well installation. The second borehole was initially advanced to 107 feet bgs using rotosonic drilling for the installation of a permanent 6-inch PVC conductor casing (sealed with Portland cement grout). The boring was then advanced to a total depth of 200 feet bgs using rotary core drilling.

- Site L (MW-71-35) - One borehole was advanced at Site L to a total depth of 71 feet bgs for well installation. The borehole was initially advanced to 37 feet bgs using rotosonic drilling methods. The rotosonic casing was then used as a temporary conductor casing to facilitate rotary core drilling, which was used to advance the borehole to total depth. The cored borehole was then backfilled with bentonite chips to form a seal from 71 feet to 39 feet. The well was then installed to a total depth of 36 feet bgs.
- Site 2 (MW-67 well series) – Two boreholes were advanced at Site 2. The initial 6-inch diameter borehole was advanced to 272.5 feet bgs using rotosonic drilling and then over-drilled with 10-inch diameter tools from ground surface to 227 feet bgs to facilitate installation of a nested well. The second borehole was advanced using rotosonic drilling to a total depth of 187 feet bgs for well installation.
- Site 3 (MW-68 well series) –Two boreholes were advanced at Site 3. The initial 6-inch diameter borehole was advanced to 250 feet bgs using rotosonic drilling and then over-drilled with 10-inch diameter tools from ground surface to 185 feet bgs to facilitate installation of a nested well. The second borehole was initially advanced to 257 feet bgs using rotosonic drilling for the installation of a permanent 5-inch steel conductor casing (sealed with Portland cement grout). The boring was then advanced to a total depth of 280.5 feet bgs using rotary core drilling.
- Site 4 (MW-69-195) – One borehole was advanced at Site 4 to a total depth of 197.5 feet bgs. The borehole was advanced to 42 feet bgs using rotosonic drilling, and then to 197.5 feet bgs with rotary core drilling using the rotosonic casing as a temporary conductor casing. The cored borehole was then over-drilled from 42 feet bgs to total depth using rotosonic methods to facilitate well installation.
- Site 5 (MW-65 well series) – One borehole was advanced at Site 5 to a total depth of 237 feet bgs. A 6-inch diameter borehole was advanced to 237 feet bgs using rotosonic drilling and then over-drilled with 10-inch diameter tools from ground surface to 167 feet bgs to facilitate installation of a nested well.
- Site 6 (MW-66 well series) - Two boreholes were advanced at Site 6. The initial 6-inch diameter borehole was advanced to 234 feet bgs using rotosonic drilling and then over-drilled with 10-inch diameter tools from ground surface to 167 feet bgs to facilitate installation of a nested well. The second borehole was initially advanced to 248 feet bgs using rotosonic drilling for the installation of a permanent 5-inch steel conductor casing (sealed with Portland cement grout). The boring was then advanced to a total depth of 271 feet bgs using rotary core drilling.

DEPTH AND ELEVATION BELOW SURFACE (ft)	CORE RUN, LENGTH, AND RECOVERY (%)	DISCONTINUITIES: R Q D (%)	DISCONTINUITIES: FRACTURES PER FOOT	DISCONTINUITIES: DESCRIPTION (DEPTH, TYPE, ORIENTATION, ROUGHNESS, PLANARITY, INFILLING MATERIAL AND THICKNESS, SURFACE STAINING, AND TIGHTNESS)	SYMBOLIC LOG	LITHOLOGY (ROCK TYPE, COLOR, MINERALOGY, TEXTURE, HARDNESS, WEATHERING, AND ROCK MASS CHARACTERISTICS)	COMMENTS (SIZE AND DEPTH OF CASING, FLUID LOSS, CORING RATE AND SMOOTHNESS, CAVING ROD DROPS, TEST RESULTS, ETC.)
			0			**Conglomerate (Tmc)** 145.5-153.1' - moderate reddish orange, (10R 6/6), no dominant clast mineralogy, fine to coarse grained, medium strong (R3), completely weathered, matrix-supported, foliated	
			0				
			0				
			0	153.5, 154.5' - Mechanical break, 35 deg, undulating to planar, brownish with black staining, no infill, slickensided, tight		**Metaconglomerate (Tmc)** 153.1-154.6' - dark yellowish orange, (10YR 6/6), strong (R4), unweathered, massive, moderate HCl reaction, conglomerate matrix has been largely replaced with minerals that have a moderate reaction with HCl, however relict conglomerate structure is apparent.	R9 = 17.5 min
			0				
155	154.9			154.6-155.6' - Fracture zone, healed fractures with random orientation			
			>10				
	R10 4.8 ft 100%	58	0			**Altered Metadiorite (pTbr)** 154.6-155.6' - moderate yellowish brown, (10YR 5/4), largely felsic mineralogy, medium grained, strong (R4), unweathered, no HCL reaction, portions of this interval exhibit mylonitic texture	
			0				
			1	158.2' - Joint, 60 deg dip along multiple planes, rough, undulating, < 1 mm calcite infilling covering 50% of one plane, yellowish staining, tightness uncertain		**Metadiorite (pTbr)** 155.6-191.9' - dusky yellowish green, (10GY 3/2), intermediate (dioritic) mineralogy, fine to medium grained, strong (R4), unweathered, massive to foliated	General Note: The metadiorite bedrock exhibits many small healed fractures (1-3 mm) of somewhat random orientation. These healed fractures create weaknesses in the rock. It can be difficult to determine if the metadiorite is jointed in-situ, or if the discontinuities are caused by the drilling method. Intervals with fracture per foot counts >10 are likely caused by drilling.

LOCATION : Site A (2100612.1 N, 7616131.8 E)
ELEVATION : 521.8 ft
DRILLING CONTRACTOR : Boart Longyear (D. Roberts)
DRILLING EQUIPMENT AND METHOD : Track-mounted Rig, Rotosonic drill head and tools
ORIENTATION : Vertical
WATER LEVELS : Approx. 66 ft BGS
START : 1/29/2009
END : 3/27/2009
LOGGER : A. Brewster (Northstar)

DEPTH BELOW EXISTING GRADE (ft)	INTERVAL (ft)	RECOVERY (in)	LAB SAMPLE	USCS CODE/ LITHOLOGY	SOIL DESCRIPTION: SOIL NAME, USCS GROUP SYMBOL, COLOR, MOISTURE CONTENT, RELATIVE DENSITY OR CONSISTENCY, SOIL STRUCTURE, MINERALOGY	SYMBOLIC LOG	COMMENTS: DEPTH OF CASING, DRILLING RATE, DRILLING FLUID LOSS, TESTS, AND INSTRUMENTATION
	1.5 2.0	COMPLETE	14:00	ML	**Silt With Sand(ML)** 0.0-2.0' - brown, (7.5YR 4/4), dry, loose, 0% gravel, 20% sand, 80% fines, sand is angular to subangular, poorly graded, no dominant mineralogy		Boring initially drilled to 65.5' bgs using Rotosonic tools up to 10-in in diameter. Permanent 6-in PVC conductor casing installed from ground surface to 65.5' bgs (portland cement grout). Boring drilled from 65.5' bgs to an initial total depth of 115' bgs using diamond bit rotary core tools (HQ-size, 3.8-in diameter). Following testing, boring was deepend to a total depth of 206' bgs using rotary core tools.
5				GM	**Silty Gravel With Sand(GM)** 2.0-17.0' - brown, (7.5YR 4/3), dry, loose, 40% gravel, 30% sand, 30% fines, gravel is angular to subangular, poorly graded, no dominant mineralogy, matrix supported, max clast size = 90 mm.		
10							
15							
	19.0 20.0		14:50	SM	**Silty Sand With Gravel(SM)** 16.0-51.0' - brown, (7.5YR 4/3), dry, loose, 15% gravel, 60% sand, 25% fines, gravel is angular to subrounded, poorly graded, no dominant mineralogy, matrix supported, max clast size = 100 mm

	60.0					**Metadiorite (pTbr)** 60.0-62.0' - Metadiorite.Highly weathered.	
						Metadiorite (pTbr) 62.0-65.5' - Metadiorite. Rock is competent, but shattered and partially pulverized by Rotosonic drilling method.	
65							
	65.5		>10	65.5-70.0' - core recovered, but largely broken by drilling.		**Metadiorite (pTbr)** 65.5-206.0' - dusky yellowish green, (10GY 3/2), intermediate (dioritic) mineralogy, medium grained, strong (R4), unweathered, massive to foliated	65.5': Begin rotary core drilling General Note: The metadiorite bedrock exhibits many small healed fractures (1-3 mm) of somewhat random orientation. These healed fractures create weaknesses in the rock. It can be difficult to determine if the metadiorite is jointed in-situ, or if the discontinuities are caused by the drilling method. Intervals with fracture per foot counts >10 are likely caused by drilling.

	68.0		0			**Metadiorite (pTbr)** 63.0-112.4' - dusky yellowish green, (10GY 3/2), intermediate (dioritic) mineralogy, fine grained, hard to very hard, unweathered, massive to foliated, pale greenish yellow (10YR 8/2) banding throughout	General Note: The metadiorite bedrock exhibits many small healed fractures (1-3 mm) of somewhat random orientation. These healed fractures create weaknesses in the rock. It can be difficult to determine if the metadiorite is jointed in-situ, or if the discontinuities are caused by the drilling method. Intervals with fracture per foot counts >10 are likely caused by drilling.

0		COMPLETE		SM	**Silty Sand (SM)** 0.0-4.5' - dark yellowish brown, (10YR 4/4), dry, loose, 5% gravel, 80% sand, 15% fines, angular to subangular, poorly graded, no dominant mineralogy, matrix supported, max clast size = 30 mm		This log is the combination of two adjacent boreholes. Boring initially drilled to 21.0' bgs using Rotosonic tools up to 6-in in diameter. 6-in Rotosonic casing then used as temporary conductor casing to facilitate rotary core drilling. Boring drilled from 21.0' bgs to a total depth of 65.0' bgs using diamond bit rotary core tools (HQ-size, 3.8-in diameter) and then overdrilled to total depth using 6-in Rotosonic tools. Adjacent borehole (approximately 10' southeast) was drilled to 75' bgs using Rotosonic tools up to 10-in diameter. Permanent 6-in PVC conductor casing installed from ground surface to 75' bgs (portland cement grout). Boring drilled from 75' bgs to a total depth of 191.5' bgs using diamond bit rotary core tools (HQ-size, 3.8-in diameter).
5					**Conglomerate (Tmc)** 4.5-21.0' - reddish brown, (5YR 4/4), dry, consolidated, no dominant clast mineralogy. Drilling method pulverizes most of the core.

As-Built Information

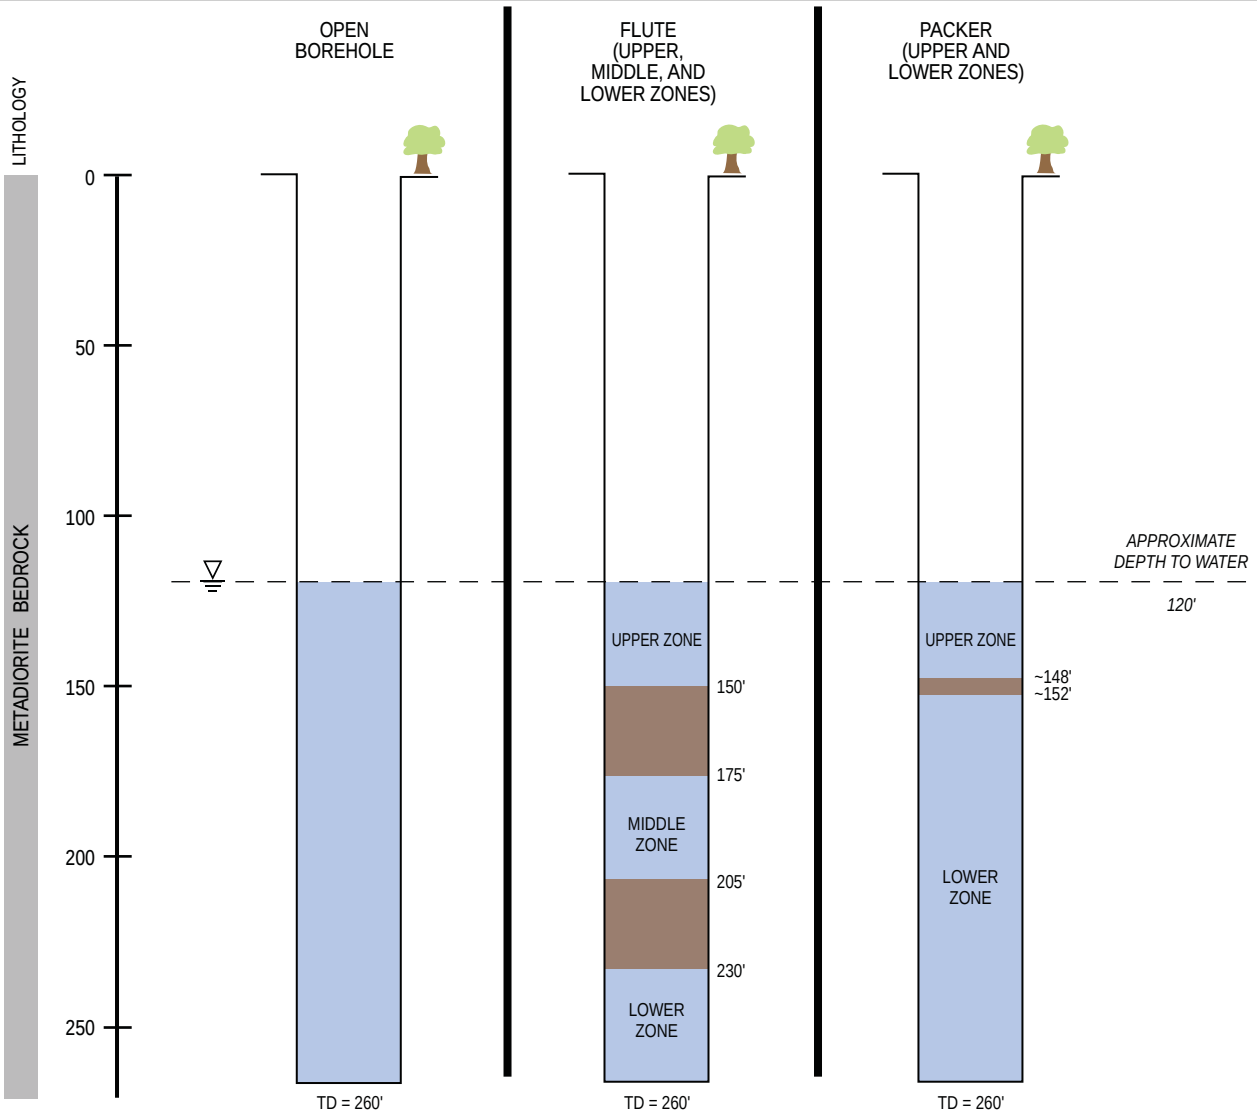
Job # 968-3

General:

Job Description:	258' 4"dia. 3 Port Water FLUTe
Customer:	CH2M Hill
Location:	155 Grand Ave. Suite 1000 Oakland, CA 94612
Well Designation:	MW-64BR
Hole Depth:	258'
Water Table:	120'
Drilling Method:	N/A
Casing Information:	N/A
Installation Method:	Water eversion
Bubbler / Tag:	120'



Liner:

Material:	210d Orange d/c 2 sleeve
Diameter:	4"
Material Above Casing:	3'
Uneverted Material:	4'
Rough Fabrication Legnth:	268'
Termination:	End Seal Knot
Knot Diameter Allowance:	2"
Markings on Liner:	Ink stamp indicating FLUTe TOC & FLUTe Job# 968-3
Spacer Design:	2 Material helix cut spacer Design (orange mesh) and Mylar

Spacer #	Spacer Bottom [ft]	Spacer Top [ft]
1	150'	120'
2	205'	175'
3	258'	230'

Tubing & Ports:							
Tubing In Bundle:			NYLON & PVDF				
Tubing In Sleeves:			NYLON & PVDF				
Bubbler Details:			1/4 NYLON				
Port Design:			Superthane feed thru				
Port Locations:			6" @ bottom of spacer				
Vent Design:			1/4 Superthane feed thru w/ 3/8 tygon tubing connected to duct				
Vent Location:			262'				
Pump Assembly:							
Port #:	**Transducer Serial #:**	**Transducer Pressure Rating [psi]:**	**Diaphragm Depth [ft. btoc]**	**Cable Serial #:**	**Cable Length [ft.]**	**Brass Elbow Depth [ft. btoc]**	**5/8" Tube Depth [ft. btoc]**
1	147349	100	218'	222554	228'	214'	199'

RE Hydrophysical Logging and Wireline Straddle Packer Testing, PG&E Topock Compressor Station, Needles, California

Dear Mr. Cavalier:

RAS, Inc., Integrated Subsurface Evaluation (RAS) is pleased to provide this draft letter report of hydrophysical logging (HPL) and wireline straddle packer (WSP) testing at the PG&E site in Topock, California. This letter report presents the results from our HPL and WSP conducted in wells MW-60BR and MW-70BR.

INTRODUCTION

During the period from October 11 through November 7, 2011, RAS conducted borehole hydrophysics in two wellbores at the PG&E Topock Compressor Station in Needles, California. This work was performed for Northstar Environmental Remediation of Lake Forest, CA (Northstar) under contract to CH2MHill of Oakland, CA, in support of their contaminant migration investigation.

The objective of this work was to employ borehole hydrophysical and packer pressure testing methods to provide additional data for evaluation of the groundwater contaminant plume and to evaluate preferential groundwater migration pathways at the subject site.

Details of field activities can be found in the field notes and daily reports Appendix A of this report. Data processing and analysis notes for each well are included in Appendix B. Data montages are included in Appendix C.

SCOPE OF WORK

Well MW-60BR

RAS mobilized to Needles, California on October 10 and 11, 2011 and arrived at the site at approximately 1030 hours on October 11, 2011. Upon arrival at the site, RAS staff met with Mike Cavaliere of CH2MHill and discussed the scope of work to be conducted and the planned schedule. RAS also attended a site health and safety briefing, with CH2MHill staff.

On October 11, RAS conducted site setup activities at MW-60BR, which included equipment set up and check out, tool calibration, and initial decontamination of all downhole equipment. As reported by CH2MHill staff, MW-60BR was drilled to an approximate total depth of 244 feet below ground surface (ft bgs). PVC surface casing was installed to a depth of approximately 136 ft bgs. A casing stick-up height of 0.91 feet was measured for reference, however all depths were measured and reported herein as from ground surface. Ambient depth to water was measured at 98.51 ft bgs. Also, on October 11, RAS conducted an ambient fluid electrical conductivity (FEC) and temperature log. After which, an extraction pump (inlet at 243 ft bgs) was installed.

On October 12, 2011 RAS conducted a second ambient FEC and temperature log in this well, and began generation of deionized (DI) water for emplacement in preparation for ambient flow characterization (AFC). The ambient FEC and temperature log are presented in the HPL processing notes in Appendix B. The FEC log displays no significant step changes with depth. However a slight increase with depth is noted. The temperature log displays a typical geothermal gradient with a distinct increase in temperature at a depth of 236 ft bgs. The temperature increased from about 27 to 28.5 degrees Centigrade (C) over the saturated interval of 98.5 to 239 feet.

DI water emplacement was then conducted, and AFC initiated. Approximately 280 gallons of DI water were emplaced during AFC. Due to the slow recharge rate under ambient pressure conditions, logging was conducted over two days during recovery. FEC and temperature logs conducted during AFC on October 12 and 13 are included in Appendix B. Analysis of these logs using the centroid and integral methods suggest the presence of six water bearing intervals. However, analysis suggests an inflow rate of less than 0.001 gallon per minute (gpm) for the entire saturated interval. As such, the observable and recorded increase in FEC suggests both primary and secondary flow. As discussed below, additional flow during stressed conditions testing allowed the six intervals to be combined into two distinct flow zones for quantification. The upper four flow intervals, from 138 to 190 ft bgs, were combined and the lower two intervals from 200 to 240 ft bgs were combined.

On October 14 and 15, 2011, hydro-geologic evaluation of the subject well by slug after emplacement (SAE) testing was conducted. Two slug tests, a 20-foot removal and a 25-foot removal, were conducted on October 14. On October 15, 2011, an approximate 30-foot slug was removed. SAE logging was conducted on October 14 and 15, 2011 after removal of each slug. Analysis of the data collected during this testing suggested that the combined upper four intervals, from 138 to 190 ft was inflowing at 0.012 gpm and the lower interval from 200 to 240 was flowing at 0.14 gpm. These interval specific flow rates, resulted in interval specific hydraulic conductivity for the intervals at 138 to 190 and 200 to 240 ft of 0.06 and 2.07 ft/day, respectively. The HPL results also suggested that the upper and deeper flow intervals had interval specific FEC of about 20,000 µS/cm. Please refer to Appendix B for HPL data analysis details and a summary table of these results.

Upon completion of HPL in well MW-60BR, the RAS field crew demobilized from the site. RAS remobilized to the site on November 1, 2011. Based on the results of the HPL, during the second mobilization to the site on November 2 and 3, 2011, WSP conducted WSP pressure testing in well MW-60BR. On November 2, 2011, RAS installed the WSP as a single packer installation from 235 to 240 feet. Pressure data collected during sampling from within and above this interval suggest no apparent intra-formation hydraulic connection with the open water bearing interval.

On November 3, 2011, RAS installed a WSP at between 160 and 179 feet bgs. Upon completion of inflation, and isolation of the 19-foot packed interval, development pumping was conducted from the packed interval and pressure was logged within and both above and below the packed interval. A steady decrease in pressure in the zone above the packers (above 158 feet) during pumping suggests a hydraulic connection between the packed interval and the shallower portion of the aquifer.

Also on November 3, 2011, RAS installed a WSP at between 140 and 149 feet bgs. Upon completion of inflation, development pumping was conducted from the packed interval and pressures were logged within and both above and below the packed interval. A steady decrease in pressure in the zone above the packers during pumping suggests a hydraulic connection between the packed interval and the shallower portion of the aquifer. Please refer to Appendix B for HPL data analysis details and a summary table of these results.

Groundwater samples were collected during each of the pumping events. Chromium IV concentrations were provided to RAS and were reported be 130 micrograms per liter (µg/L), 290 µg/L, and 78 µg/L from the intervals between 140 and 149 feet bgs, 160 and 179 feet bgs, and 235 and 240 feet bgs, respectively. These data are included on the montage for MW-60BR.

Well MW-70BR

During the period from November 3 to November 7, 2011, RAS conducted hydrophysical logging in well MW-70BR. After equipment set-up, check out and calibration, all downhole equipment was decontaminated. As reported by CH2MHill staff, MW-70BR was drilled to an approximate total depth of 225 ft bgs. PVC surface casing was installed to a depth of approximately 128 ft bgs. A casing stick-up height of 2.4 feet was measured for reference, however all depths were measured and reported herein as from ground surface. Ambient depth to water was measured at 78.0 ft bgs. On November 3, RAS installed an extraction pump (inlet at 224 ft bgs) and, prior to pump installation, conducted an ambient FEC and temperature log.

The ambient FEC and temperature log is presented in the HPL Processing Notes for well MW-70BR in Appendix B. The FEC log displays a steady increase in FEC with depth with no significant distinct step changes. The temperature log displays a typical geothermal gradient with no discerning features of note. The temperature increased from about 28 to 29.7 degrees C over the saturated interval of 128 (bottom of casing) to 224 feet.

On November 5, 2011 RAS conducted a second ambient FEC and temperature log, and then began generation of DI water for emplacement in preparation for AFC. The FEC log displays no significant step changes with depth. However as with the previous days' FEC log, a steady increase in FEC with depth is noted. The temperature log displays a typical geothermal gradient with no discerning features of note.

DI water emplacement was then conducted, and AFC was initiated. Approximately 295 gallons of DI water were emplaced during AFC. Due to the slow recharge rate under ambient pressure conditions, logging was conducted over two days during recovery (November 5 and 6, 2011). FEC and temperature logs conducted during AFC are included in Appendix B. Analysis of these logs using the centroid and integral methods suggest the presence of one, distinct water bearing interval near the bottom of the well. Analysis of data from both days suggests an overall total inflow rate of less than 0.013 gpm for the entire saturated interval, and all quantifiable flow from the one distinct interval at the bottom of the well (below 219 ft bgs). As such, the observable and recorded increase in FEC suggests a small amount of primary flow from the entire saturated interval, and some additional flow with within the one flow zone at the bottom of the well. As discussed below, no additional inflow was observed during stressed condition testing over the remaining saturated interval.

On November 7, 2011, additional aquifer evaluation by slug test (rising head) after DI water emplacement testing was conducted with a water level head displacement of about 4 to 5 feet. Three slug tests were conducted. The largest drawdown of about 5.05 feet, was measured during the third slug.

SAE logging was conducted after removal of each slug and, contemporaneously, pressure data was recorded. Analysis of these logs using the centroid and integral methods suggest the presence of very low-rate horizontal flow occurring from a single interval at the bottom of the well (below 219 feet bgs). This interval contributed all of the flow during SAE testing. The pumping rate of 3.2 gpm resulted in an estimated hydraulic conductivity for the interval below 219 feet of 14.6 ft/day. The HPL results also suggested that this single flow interval had interval specific FEC of about 16,000 µS/cm. Please refer to Appendix B for HPL data analysis details and a summary table of these results.

Upon completion of HPL in well MW-60BR, the RAS field crew demobilized from the site.

CONCLUSIONS

Ambient flow characterization (native flow during ambient or background pressures conditions) was conducted in each well. In both wells, ambient flow was observed to be occurring at extremely low flow rates during the period of our testing. Overall ambient flow ranged from less than 0.001 to 0.013 gallons gpm. The lowest ambient flow was observed in well MW-60BR, where flow over the entire water bearing intervals (possibly via primary porosity) occurred at less than 0.001 gpm. The highest ambient flow rate was observed in Well MW-70BR at 0.013 gpm for the single water bearing interval.

Flow evaluation was also conducted during stressed conditions where flow was induced into the wellbore by slug testing methods. Aquifer conditions did not permit constant rate pumping to be conducted and were such that slug test procedures were required. The results of this testing suggested that the water bearing intervals are very low flowing units. The lowest interval specific flow rate occurred over the entire saturated portion of well MW-60BR (0.012 gpm) and the greatest interval specific flow rate occurred in Well MW-70BR of 3.2 gpm.

Hydraulic conductivity estimates were intended to be preliminary in nature and were not based on any site specific algorithms that may have been developed by others. Estimates are presented in the summary table for each well. In summary, the resulting interval specific hydraulic conductivity estimates ranged from 0.06 to 14.6 feet per day.

MW-60BR

Analysis of the data collected during AFC and SAE testing in well MW-60BR supports the very low flow ambient condition and suggests the presence of both primary and secondary flow. Analysis of the data suggests that the total ambient flow for the water bearing intervals was less than 0.001 gpm. No distinct flow zones

could be identified during ambient flow, suggesting primary flow with no preferential flow paths.

During SAE, the overall flow rate for the entire saturated interval was approximately 0.15 gpm. While six distinct flow zones were identified, the extremely low flow rate prevented quantification of flow without combining intervals. The very low inflow rate is also supported by the water level recovery curve. Based on the rising head data, a hydraulic conductivity based on Hvorslev (1951) of 2.07 feet per day was calculated for the productive flow zone at the bottom of the well.

Results of packer pressure testing in MW-60BR suggests a hydraulic connection between the packed intervals (160 to 179 and 140 to 149 feet) and the upper portions of the aquifer.

The HPL results also suggested an interval specific formation water concentration of 20,000 µS/cm for the saturated interval.

MW-70BR

Analysis of the data collected during AFC and SAE testing in well MW-70BR supports the very low flow ambient condition and suggests the presence of primary flow. Analysis of the data suggests that the total ambient flow over the entire saturated interval was less than 0.013 gpm. No distinct flow zones could be identified during ambient flow, suggesting primary flow with no preferential flow paths.

Analysis of data collected during SAE testing suggests the presence of one, distinct water bearing interval near the bottom of the well (below 219 ft bgs). Based on the rising head data, a hydraulic conductivity of 14.6 feet per day was calculated for the single identified water bearing interval at a depth of 220 to 229 feet (total depth).
The HPL results also suggested an interval specific formation water concentration of 16,000 µS/cm for the saturated interval.

Please refer to Appendix B for HPL data analysis details and a summary table of the results for each well.

We appreciate the opportunity to work with you on this project.

Please call with any questions.

Best Regards,
RAS, Inc.

WELL COMPLETION DIAGRAM

PROJECT :	ER-TCS Investigation	LOCATION :	Site H
DRILLING CONTRACTOR :	Boart Longyear (Dale / Brigham)	DRILLING METHOD: Sonic and HQ Rotary	EQUIPMENT RS-350
START DATE: 10/19/11	TIME:	END DATE: 10/22/11	TIME:
WATER LEVEL READINGS AND TIMES:	84 feet bgs	LOGGER:	A. Brewster

Component Depths in feet BGS

128.0 ft bgs Bottom of grout
128.0 ft bgs Bottom of transition sand

227.0 ft bgs Bottom of boring (hard bottom sounding)

1- Ground elevation at well	541 ft amsl
a) Northing	
b) Easting	
2- Top of casing elevation	
a) Stickup (feet above gs)	
3- Diameter of boring (inches)	9 inches to 128 ft bgs, 3.8 inches from 128 - 227
4- Wellhead protection cover type	
a) Concrete pad dimensions	
5- Material of well casing	Sch. 40 PVC
a) Diameter of well casing (inche	5
6- Grout mix used	Type II/V Portland Grout
a) Method of placement	Tremmie Pipe
b) Volume of grout (gallons)	300 gallons
7- Type of seal	N/A
a) Quantity used (pounds)	N/A
8- Transition sand	No. 60 Monterey Sand
a) Quantity used (pounds)	100 pounds
9- Type of screen pack	N/A
a) Quantity used (pounds)	N/A
10- Screen type	N/A
a) Slot size (inches)	N/A
b) Total screen length (feet)	N/A
11- Sump / end cap type	N/A
a) Length (feet)	N/A
12- Centralizer type	5" Stainless Steel
a) Depths (feet)	200, 150, 100, 50

Comments Open borehole from 128 to 227 feet bgs.

NOTE: DRAWING NOT TO SCALE

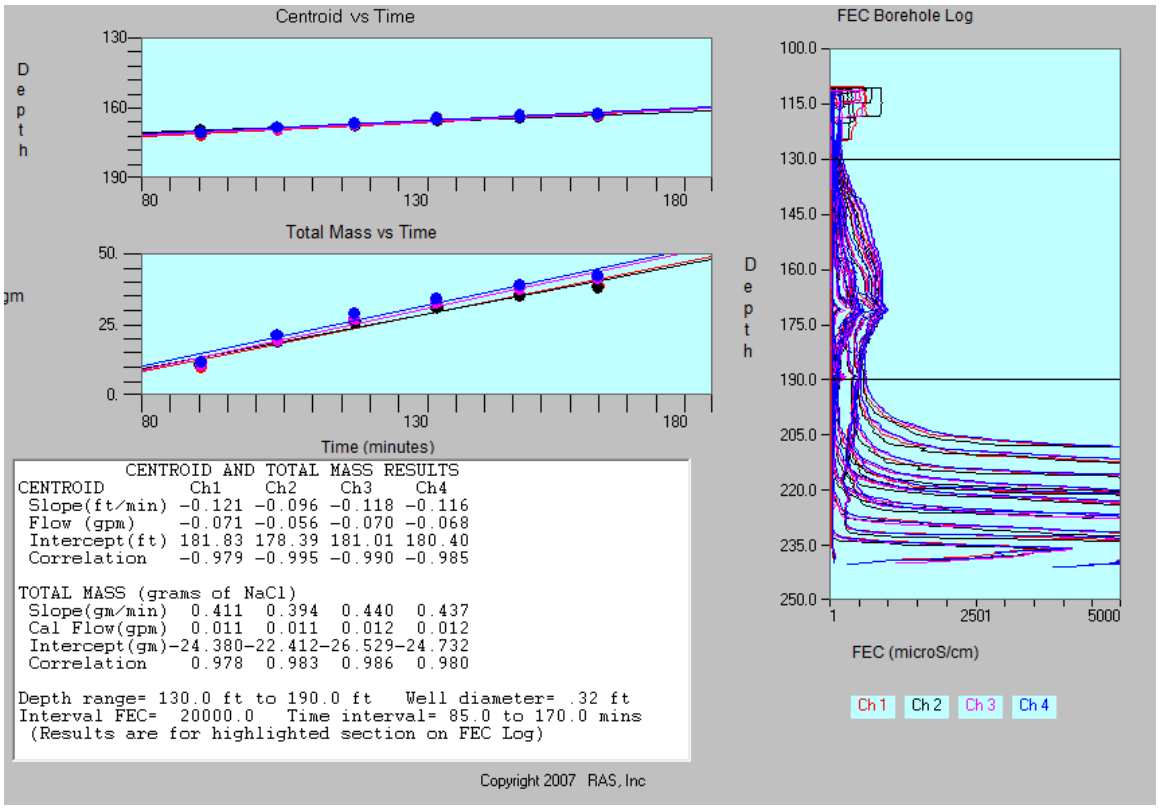

Figure 20. MW-60BR-245 - Analysis results of logs for Slug Test After Emplacement Testing. Interval from 130 to 190 ftbtoc. Late logs from 28-foot slug. Total flow = 0.012 gpm (average flow of four channels). 15 Oct 2011.

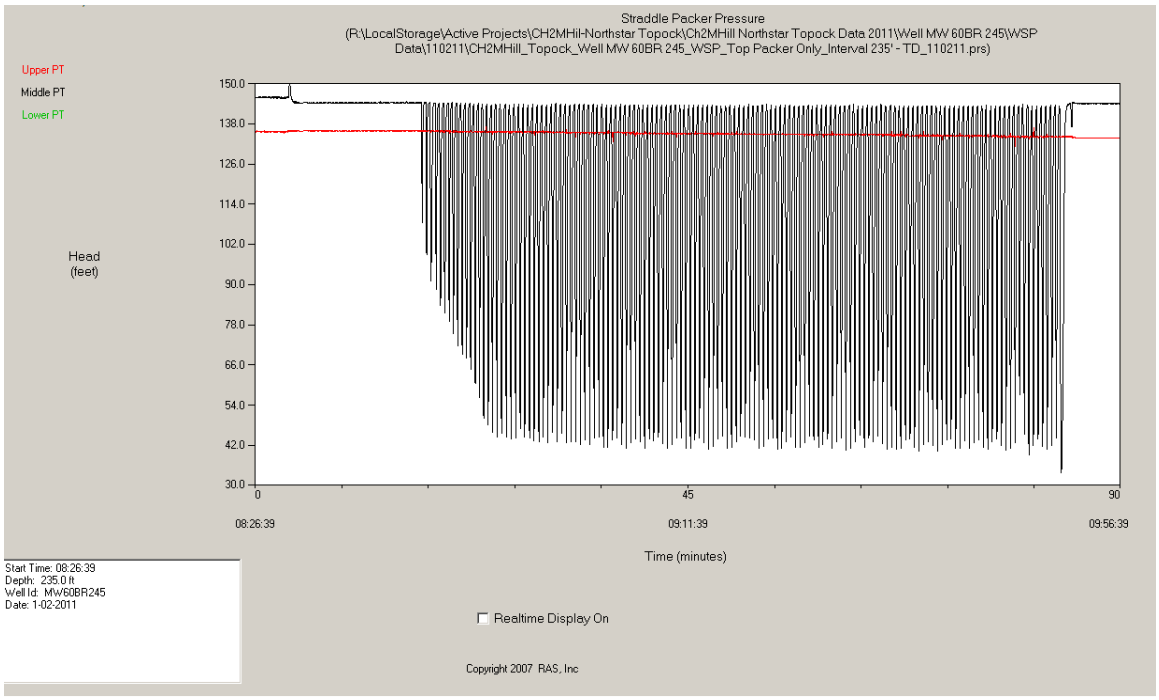
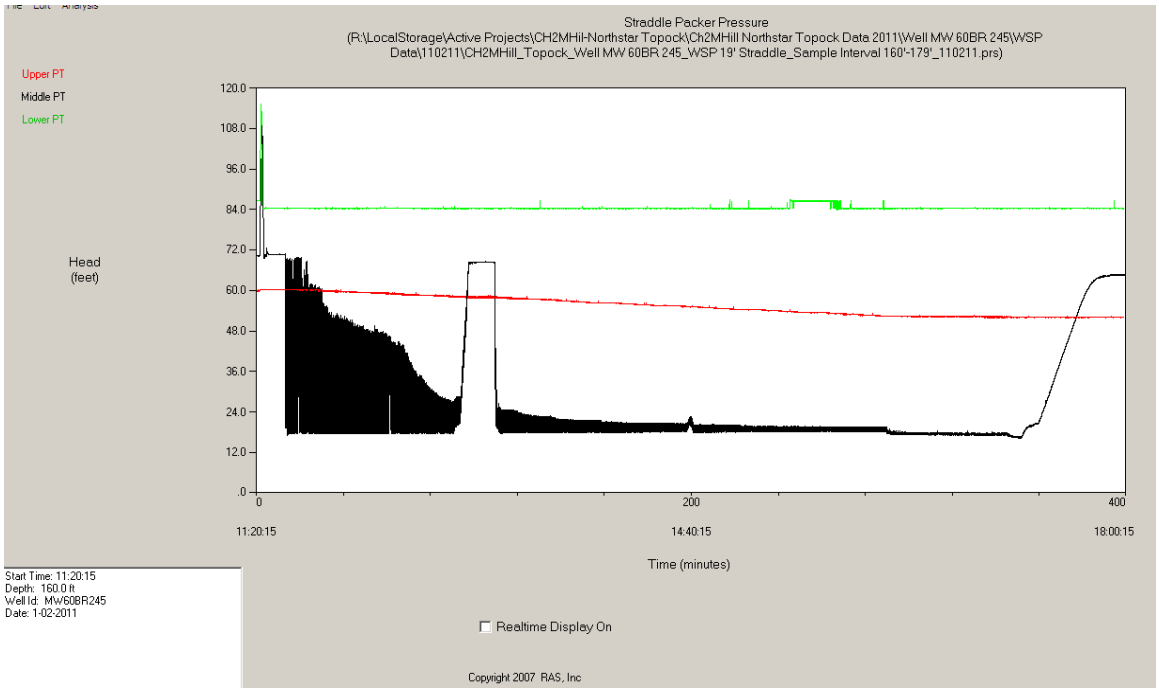
RAS Inc. Copyright RAS, Inc. 2012.





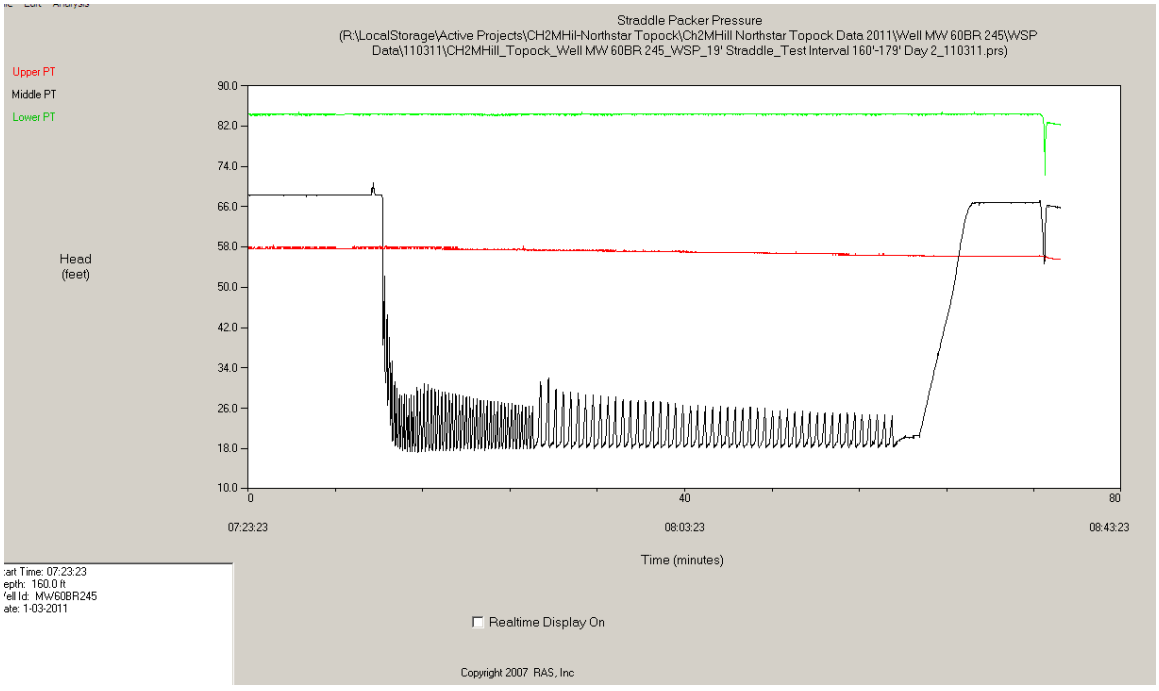


Figure 21. MW-60BR-245 Wireline Straddle Packer (WSP) pressure results during sampling at interval 235 to 240 ftbtoc. Single packer inflated. No apparent intra-formation hydraulic communication with open water bearing interval suggested by upper pressure transducer response. 2 Nov 2011.

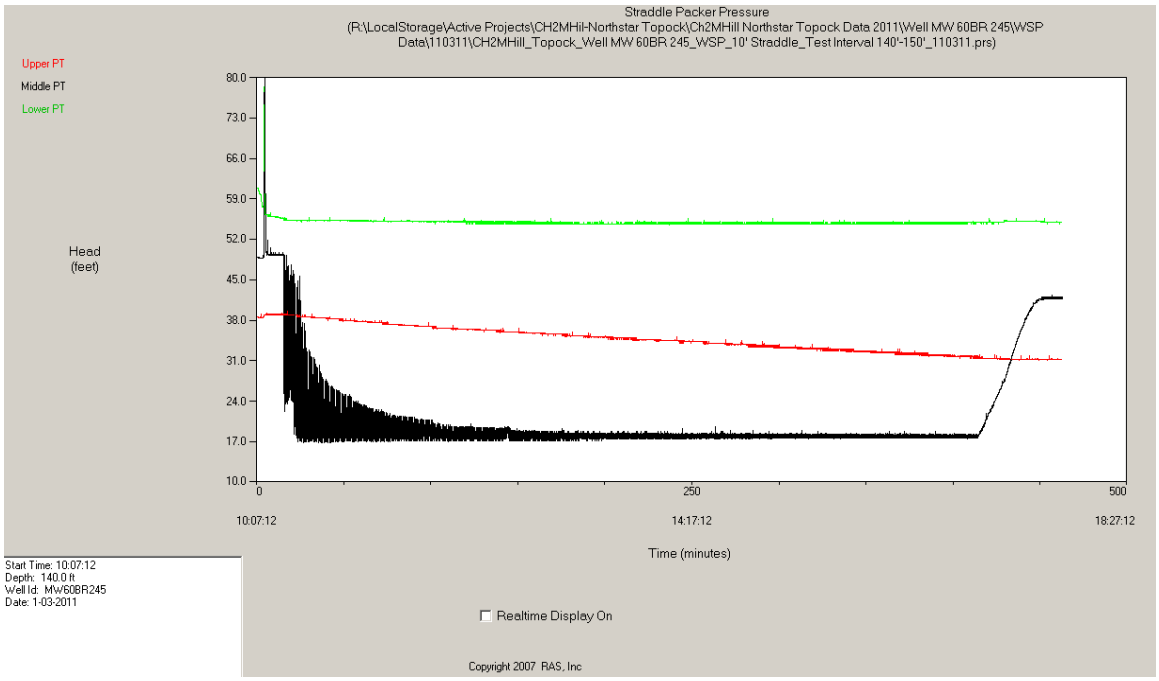
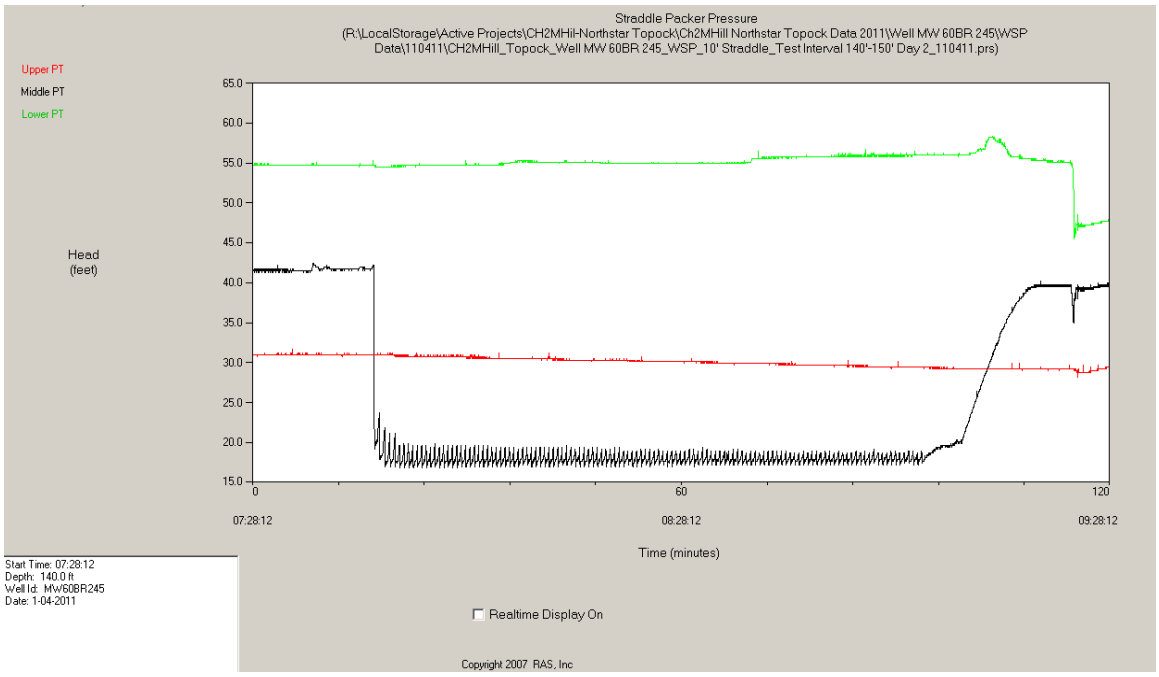
RAS Inc. Copyright RAS, Inc. 2012.



(Day 1, 2 Nov 2011)



(Day 2, 3 Nov 2011)

Figure 22. MW-60BR-245 WSP pressure results during development pumping at interval 160 to 179 ftbtoc days 1 (upper) and 2 (lower). Straddle packers inflated. Steady decrease in upper pressure transducer (red trace) during pumping period suggests hydraulic connection within formation to upper portion of aquifer.

RAS Inc. Copyright RAS, Inc. 2012.

(Day 1, 3 Nov 2011)

(Day 2, 4 Nov 2011)

Figure 23. MW-60BR-245 WSP pressure results during development pumping at interval 140 to 150 ftbtoc days 1 (upper) and 2 (lower). Straddle packers inflated. Steady decrease in upper pressure transducer (red trace) during pumping period suggests hydraulic connection within formation to upper portion of aquifer.

RAS Inc. Copyright RAS, Inc. 2012.

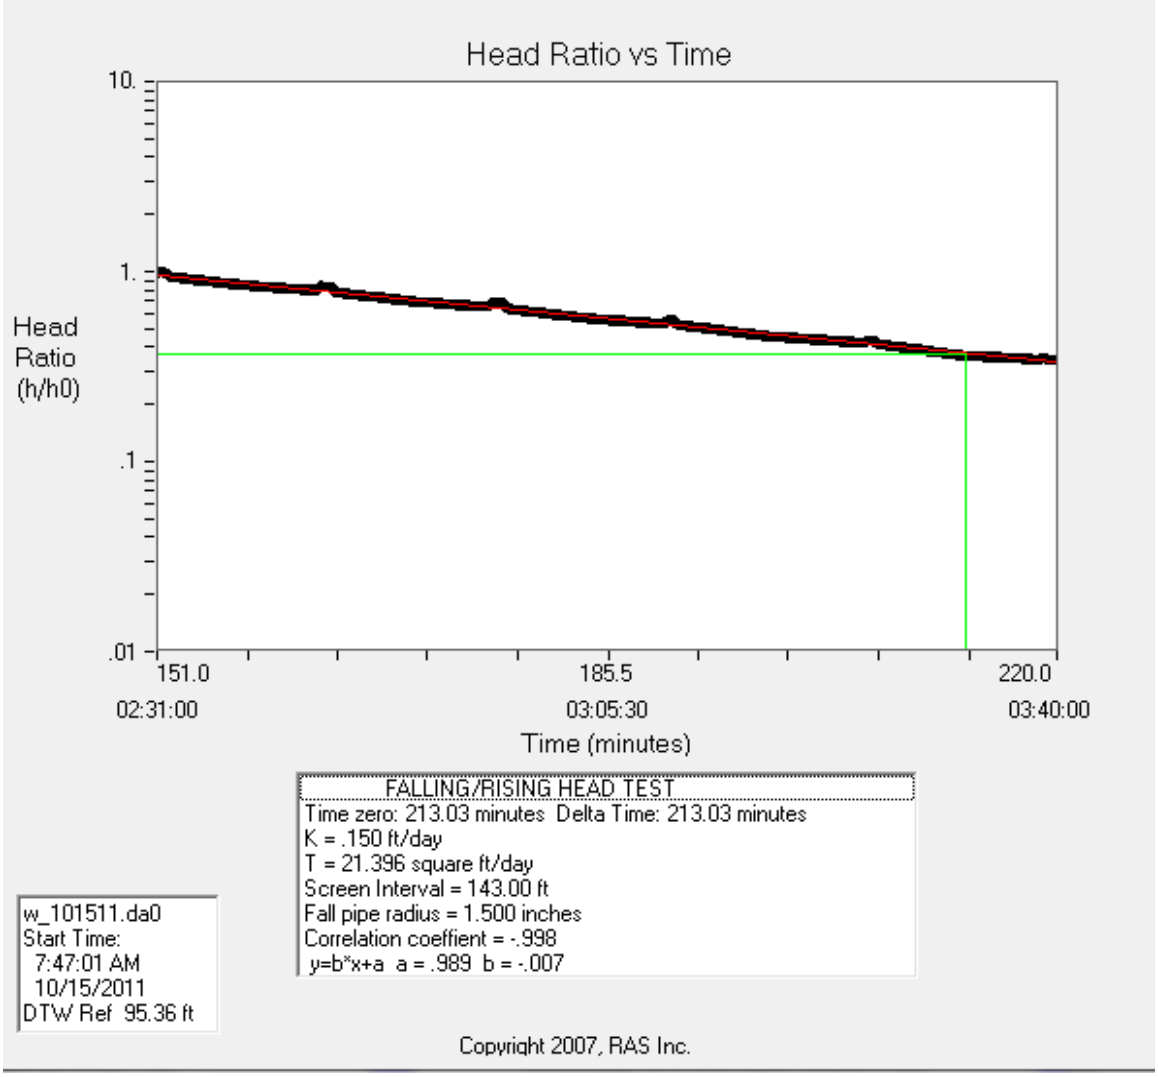


Figure 24. MW60BR245. Slug test analysis from 23-foot slug. 15 Oct 2011. Interval from 95 to 238 feet. K = 0.150 ft/day. T = 21.396 ft ^{2} /day.

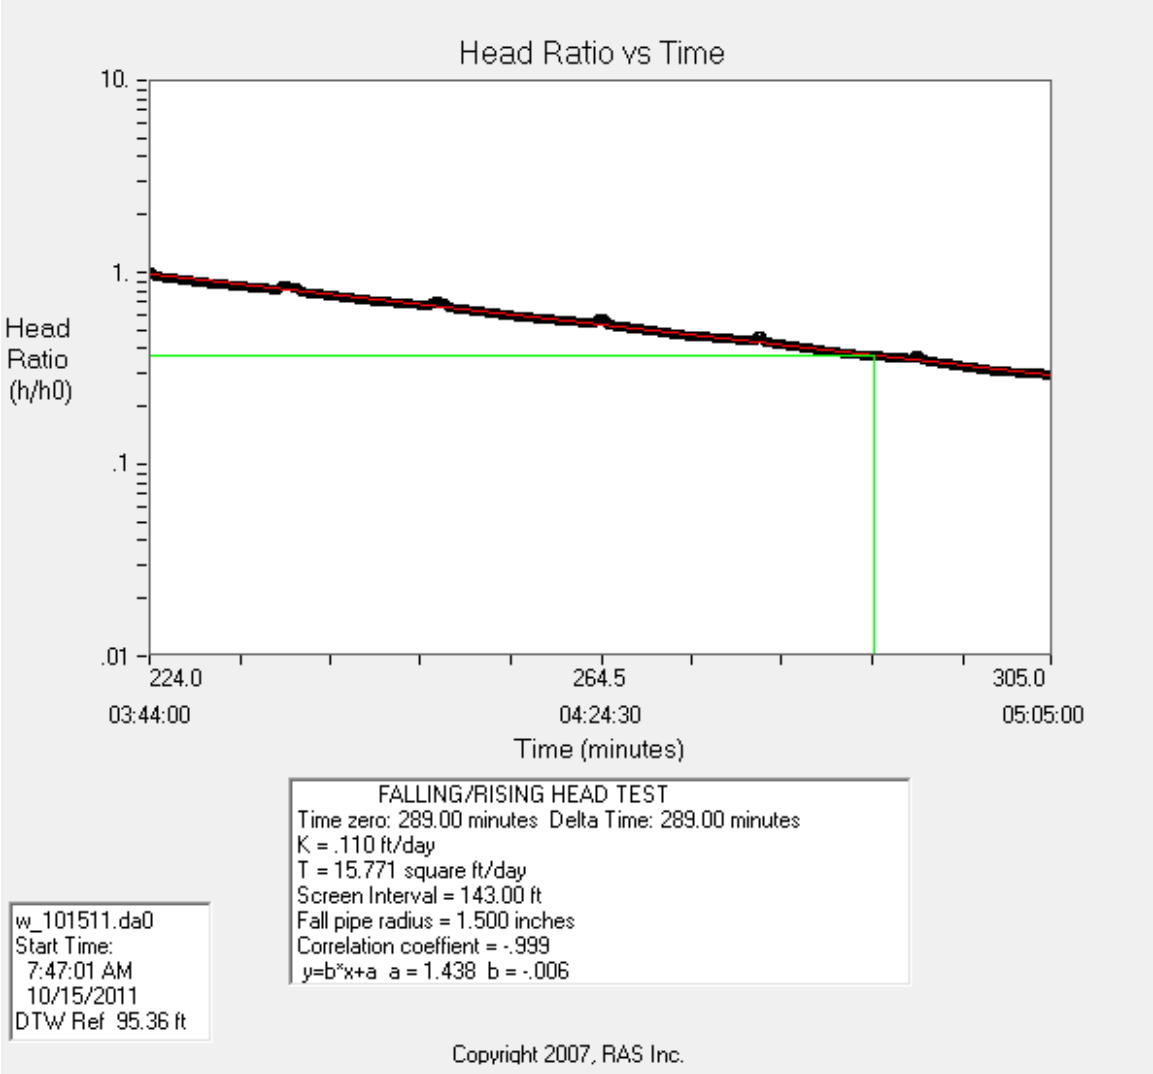

Figure 25. MW60BR245. Slug test analysis from 29-foot slug. 15 Oct 2011. Interval from 95 to 238 feet. K = 0.110 ft/day. T = 15.771 ft ^{2} /day.

Summary of HPL Results - Conductive Feature (CF) Depths						
			Interval Specific Flow Rate		Interval Specific Concentration	Interval Specific Hydraulic Conductivity
Conductive Feature	**Depth (ft)**		**Ambient**	**Rising Head Test # 2 (max qi)**	**µS/cm**	**ft/day**
	Top	**Bottom**				
1	138	146	~0.001	0.012	20,000	0.06 ft/day
2	160	163				
3	170	180				
4	188	190				
5	200	203		0.14		2.07 ft/day
6	236	240				
	Total flow observed at surface					
	Sum of Inflows			0.149		T=15.77
	ALL DEPTHS REFERENCED TO TOP OF PVC CASING					

$T_t = 15.77\ ft^2/day$

$T_t = L_t * K_t$

$T_{5-6} = 0.92 * 15.77 = 14.51\ ft^2/day$

$K_{5-6} = T_{5-6} / 7ft = 14.51\ ft^2/day / 7ft = 2.07\ ft/day$

$T_{1-4} = 0.08 * 15.77 = 1.26\ ft^2/day$

$K_{1-5} = T_{1-4} / 21ft = 1.26\ ft^2/day / 21\ ft = 0.06\ ft/day$

RAS Inc. Copyright RAS, Inc. 2012.

LEGEND

LITHOLOGY

- Alluvium
- Bedrock, Metadiorite

HYDROPHYSICAL LOGGING AND RESULTS:

Fluid Resistivity and Fluid Temperature
Log performed during ambient conditions

Interval Specific Flow rate derived from Ambient Flow Characterization (AFC) and Slug Test After Emplacement (SAE) hydrophysical data.

Horizontal flow observed during ambient conditions, inflows also evaluated during stressed (constant pumping or slug test) conditions. Horizontal flow rates based on integral method for q (Lowe, et. al., 1989) and dilution method for v (Drost, 1968).

HPL FEC logs presented were collected during Slug Test after Emplacement conditions.

- FEC 1019
- FEC 1045
- FEC 1114
- FEC 1158
- FEC 1241

FEC XXXX where XXXX is military time at start of log.

RE: Geophysical Logging, Hydrophysical Logging and Wireline Straddle Packer Testing, PG&E Topock Compressor Station, Needles, California

Dear Mr. Cavaliere:

RAS, Inc., Integrated Subsurface Evaluation (RAS) is pleased to provide this draft letter report of hydrophysical logging (HPL) and wireline straddle packer (WSP) testing at the PG&E site in Topock, California. This letter report presents the results from our HPL and WSP conducted in well MW-72BR-200.

INTRODUCTION

During the period from July 17 through July 25, 2012, RAS conducted borehole geophysics, hydrophysics, and wireline straddle packer testing in one well at the PG&E Topock Compressor Station in Needles, California. This work was performed for Northstar Environmental Remediation of Lake Forest, CA (Northstar) under contract to CH2MHill of Oakland, CA, in support of their groundwater investigation.

The objective of this work was to employ borehole hydrophysical testing and straddle packer sampling to provide additional data for groundwater contaminant evaluation and to evaluate preferential groundwater migration pathways at the subject site.

A summary table of HPL data collected form this field effort is included in Appendix A of this report. Details of field activities can be found in the field notes and daily reports Appendix B. Data processing and analysis notes are included in Appendix C. A data montage is included in Appendix D.

SCOPE OF WORK

RAS mobilized to Needles, California on July 16 and 17, 2012 and arrived at the site at approximately 1700 hours on July 17, 2012. Upon arrival at the site, RAS staff met with Arlin Brewster of Northstar and discussed the scope of work to be conducted and the planned schedule. RAS also dropped the equipment trailer on site.

On July 18, RAS attended a site health and safety briefing with Northstar and CH2MHill staff, and conducted initial decontamination of all downhole equipment. Upon completion of equipment decontamination, RAS mobilized to the well and conducted site setup activities at MW-72BR-200. Set-up included equipment set up and check out, tool calibration. Also on July 18, with the assistance of Northstar staff, RAS set up DI tanks at the potable water source at the site.

As reported by Northstar staff, MW-72BR-200 was drilled to an approximate total depth of 200 feet below ground surface (ft bgs). Temporary 3-inch PVC slotted casing was placed within the open borehole to the total depth as a precaution during borehole development activities. The top of the temporary casing was measured at 0.5 ft bgs, and the surface completion was a flush-mounted road box. However all depths were measured and reported herein as from ground surface. Ambient depth to water was measured at 58.15 ft bgs. Also, on July 18, RAS conducted an ambient fluid electrical conductivity (FEC) and temperature log. The Ambient FEC and temperature log on July 18 was conducted in the temporary 3-inch screen. RAS then installed a pressure transducer into the temporary well screen, and demobilized from the site at 1835 hours.

On July 19, 2012 RAS arrived at the site at 0650 hours and attended a health and safety briefing and then began site activities. RAS conducted tool calibration checks, and then conducted a second ambient FEC and temperature log in the temporary casing. The ambient FEC and temperature log are presented in the HPL processing notes in Appendix B. The FEC log displays four significant step changes in FEC and a significant general increase with depth is noted from about 12,000 µS/cm to about 22,000 µS/cm. The temperature log displays a thermal response typically associated with a native geothermal gradient and does not appear to be impacted by vertical advective groundwater flow in the borehole fluid column. The temperature increased from about 27 to 28 degrees Centigrade (C) over the saturated interval of 58.2 to 197 feet. Also on July 19, generation of deionized (DI) water for emplacement in

preparation for ambient flow characterization (AFC) was conducted with the assistance of Northstar staff. DI water was transported in a 300-gallon poly tank from the source to the well site by Northstar, and pumped into temporary storage tanks at the well site.

Upon completion of the ambient log, RAS removed the pressure transducer and temporary PVC well screen. The bottom of the open borehole was tagged with a measuring tape at 198.85 ft bgs. RAS then conducted a pre-log calibration check of the 3-arm mechanical caliper tool and then conducted a caliper log of the well. The caliper log suggested the bottom of the 6-inch conducted casing was at about 107 ft bgs. The open borehole below the conductor casing was approximately 3.7 inches in diameter, and the log suggested very little signature variation, one void to about 6 inches in aperture was present at about 111 ft bgs. Upon completion of the caliper log, an extraction pump (inlet at 194.5 ft bgs) was installed and the pressure transducer was reinstalled, in preparation for HPL testing. RAS conducted post-log calibration checks and left the site at 1745 hours.

On July 20, 2012 RAS arrived at the site at 0700 hours and attended a health and safety briefing and discussed the scope of work planned for the day, and then mobilized to the well. Upon arrival at the well, RAS conducted tool calibration checks, and then conducted an ambient FEC and temperature log. DI water emplacement was then conducted, and AFC initiated. Approximately 250 gallons of DI water were emplaced during AFC. Due to the low ambient flow under native pressure conditions, logging was conducted over two days during recovery. FEC and temperature logs conducted during AFC on July 20 and 21 are included in Appendix B. Analysis of these logs using the centroid and integral methods suggest the presence of three water bearing intervals. Two dominant flow features were suggested by analysis of the AFC logs, one at about 153 ft bgs, and another at the bottom of the logging interval about 191 ft bgs. However, analysis suggests an inflow rate of less than 0.01 gallon per minute (gpm) from each of these two features, and approximately 0.015 gpm for the entire saturated interval. As discussed below, additional flow testing during stressed conditions suggested the presence of four conductive features. The two additional flow features identified under stressed conditions were between 147 and 167 ft bgs, and while quantified independently during stressed conditions testing, were combined into one distinct flow zone for quantification during AFC. Flow from this combined feature during ambient conditions testing was 0.012 gpm. Equivalent in-hole velocities for each interval were estimated to be 1.0, 0.6, 0.8 and 0.7 feet per day (fpd) in-hole horizontal velocity, for conductive intervals 1, 2, 3 and 4, respectively.

Upon completion of AFC testing on July 21, RAS began hydraulic characterization (HC) testing. HC consisted of conducting one 10-foot and one 20-foot slug tests to quantify well recovery under stressed conditions. Analysis of the HC recovery data suggested that a low flow rate pumping during injection (PDI) would be feasible in this well. Upon completion of HC on July 21, RAS conducted post-log tool calibration checks, and departed the site at 1650 hours.

On July 22, 2012, RAS conducted a pre-log calibration check and an ambient FEC and temperature log. Hydro-geologic evaluation of the subject well by PDI testing was then conducted. PDI was begun with an extraction rate of about 1.4 gpm, and FEC logs were collected until three repeatable logs were noted. Then pumping during injection was begun, with at a total extraction rate of about 2.9 gpm, and an injection rate of 1.4 gpm; a net formation production of 1.5 gpm. Logging during PDI was continued until stable conditions were achieved and three repeatable logs were noted. Total drawdown during PDI was about 25.5 feet. Analysis of the data collected during this testing suggested that upper interval identified during AFC, from about 105 to 110 ft was inflowing at 0.1 gpm and the interval near the bottom of the well from 191 to TD was flowing at between 0.54 and 0.96 gpm. Because the entire interval of this conductive feature was not logged due to the presence of the pump, this range of interval specific flow rates was estimated by correlation of the HPL log data with total flow and mass balance analysis. Two additional conductive features, between 147 and 156 ft bgs, and between 161 and 167 ft bgs, were identified during PDI. Interval specific flow rates for these two features were 1.18 and 0.12 gpm, respectively. For reference purposes, the HPL data summary table included in Appendix A numerically identifies these four conductive features as 1 through 4, with increasing depth.

These interval specific flow rates, resulted in interval specific hydraulic conductivity for the intervals 1 through 4, at 0.16, 1.16, 0.16 and between 0.67 and 1.21 ft/day, respectively. The HPL results also suggested that FEC ranged between 12,700 and 24,000 µS/cm. Please refer to Appendix B for HPL data analysis details.

Upon completion of PDI well MW-72BR-200 on July 22, 2012 RAS conducted a post-log calibration check, and then removed the pump and piping in preparation for wireline straddle packer (WSP) testing and then demobilized from the site at 1830 hours.

On July 23, 2012 RAS arrived at the site at 0705 hours, attended a health and safety briefing, discussed the scope of work planned for the day, and then mobilized to the well to begin WSP testing and sampling. After checking tool operation on the surface, RAS installed the WSP as a double packer installation from 148 to 168 feet. Upon completion of inflation, and isolation of the 20-foot packed interval,

development pumping was conducted from the packed interval and pressure was logged within and both above and below the packed interval. Pressure data collected during pumping and sampling from within, above, and below this interval suggest no apparent intra-formation hydraulic connection. Upon extraction of approximately three borehole volumes (estimated as 10.5 gallons in the packed interval) and stabilization of extraction water parameters, a sample was collected from this interval. Approximately 33 gallons of groundwater was pumped from the interval prior to sampling.

On July 24, 2012 RAS arrived at the site at 0700, attended a health and safety briefing, and then mobilized to the well to begin additional WSP testing and sampling in the well. RAS installed the WSP as a double packer installation from 110 to 130 feet. HPL data suggested a conductive feature between approximately 105 and 110 feet. As reported by Northstar, the borehole telescopes to a 3.8-inch open hole at about 107 feet bgs. RAS set the packer with the upper bladder as shallow as was practicable given the large difference in borehole diameter above 107 feet.

After completion of inflation, and isolation of the 20-foot packed interval, development pumping and sampling was conducted from the packed interval and pressure was logged within and both above and below the packed interval. Pressure data collected during pumping from within the packed interval suggested very little flow in this zone and that sampling was not feasible, given the volumes needed. As such, at the direction of CH2MHill, RAS deflated the packer and brought it back to the surface in preparation for sampling a third zone.

RAS then reconfigured the packer as a single packer set and set the packer at 191 feet to isolate the lower portion of the borehole. Upon completion of inflation, development pumping was conducted from the packed interval (191 to 198.5 feet) and pressures were logged within and both above the packed interval. Pressure data collected during pumping and sampling from within and above this interval suggest no apparent intra-formation hydraulic connection. Upon extraction of approximately three borehole volumes (estimated as 3.5 gallons in the packed interval) and stabilization of extraction water parameters, a sample was collected form this interval. Approximately 11.5 gallons of groundwater was pumped from the interval prior to sampling. Please refer to Appendix B for HPL data analysis details.

Groundwater samples were collected from the interval between 148 and 168 ft bgs, and from the interval between 191 and the bottom of the borehole. Chromium VI concentrations, which were analyzed at an offsite laboratory and reported to RAS by CH2MHill to be 2.0 µg/L for the interval from 148 to 168 ft bgs and below the reporting limit of 1.0 µg/L (not detected) for the interval near the bottom of the well at 191 to 198.5 ft bgs. These data are included on the montage for MW-72BR-200.

On July 25, 2012, RAS conducted equipment decontamination, packed and secured equipment and demobilized from the site.

CONCLUSIONS

Ambient flow characterization (native flow during ambient or background pressures conditions) was conducted in the well. Ambient flow was observed to be occurring at extremely low flow rates during the period of our testing. Overall ambient flow of 0.015 gpm was measured in the well. The dominant flow zone was between 147 and 167 ft bgs. While two conductive features were identified in this interval during PDI, they were combined into one feature for quantification during AFC. A combined 0.012 gpm was measured from within this interval; or 80% of the total flow measured during AFC. The remaining 20% of the inflow, or 0.003 gpm, were from the remaining two conductive features between 105 and 110, and between 191.5 and 198.5 ft bgs.

Under ambient conditions, the equivalent in-hole velocities for each interval were estimated to be 1.0, 0.6, 0.8 and 0.7 fpd in-hole horizontal velocities, for conductive intervals 1, 2, 3 and 4, respectively.

Flow evaluation was also conducted during stressed conditions during PDI testing. The results of this testing suggested that the water bearing intervals are low to moderate flowing units, however the increase in flow rate during PDI suggested moderate transmissivity in these features. Interval specific flow rates measured or estimated during PDI ranged from 0.10 gpm in the upper conductive feature between 105 and 110 ft bgs, to 1.18 gpm in the dominant feature between 147 and 156 ft bgs. Flow from this feature was 60.8 % of the estimated flow during PDI. Flow from the feature near the bottom of the well between 191.5 and 198.5 ft bgs was 27.8 % of the total estimated flow; the two features combining for a total of 88.7 % of the total flow.

The interval specific hydraulic conductivities in well MW-72BR-200 ranged from 0.16 feet per day (fpd) in the zone between 105 and 110 ft bgs, to 1.18 fpd in the dominant flow zone between 147 and 156 ft bgs. The interval specific hydraulic conductivity for the interval near the bottom of the well between 191.5 and 198.5 ft bgs is expressed as a range between 0.67 and 1.21 fpd, using the lowest and the highest estimated interval specific flow values from the analysis.

Hydraulic conductivity estimates were intended to be preliminary in nature and were not based on any site specific algorithms that may have been developed by others. Estimates are presented in the summary table in Appendix A. In summary, the resulting interval specific hydraulic conductivity estimates ranged from 0.16 to 1.21 fpd.

SUMMARY

Analysis of the data collected during AFC and PDI testing in well MW-72BR-200 supports the very low flow ambient condition and suggests the presence of primary flow. Analysis of the data suggests that the total ambient flow over the entire saturated interval was approximately 0.015 gpm.

Analysis of data collected during PDI testing suggests the presence of four distinct water bearing intervals, with two co-dominate flow zones; between 147 and 156 ft bgs, and between 191.5 ft bgs and the bottom of the well (198.5 ft bgs).

Based on the HPL data, interval specific hydraulic conductivity ranged from between 0.16 fpd to 1.24 fpd. During PDI, the overall flow rate for the entire saturated interval was estimated at between 1.94 and 2.36 gpm. The HPL and WSP results also suggested an interval specific formation water concentration of between 12,700 and 24,000 µS/cm for the saturated interval, with a general increasing downward trend.

Results of WSP sampling in MW-72BR-200 suggest that Chromium VI concentration of 2.0 µg/L was present in the sample collected from between 148 and 168 ft bgs. The sample collected near the bottom of the well at between 191 and 198.5 ft bgs was reported to have no detectable concentrations (< 1.0 µg/L).

We appreciate the opportunity to work with you on this project.

Please call with any questions.

Best Regards,
RAS, Inc.

Steven R Truesdale

1244						- Stopped @ 80' to do a pumptest
1305						- Bladder pump test beginning
1325						- Water being pumped out for our pumptest ~~* Not really a test~~ * Slight drop in head in PT data
1334						~~-~~ - Continuing to lower WSP
1335						- Hanging up trying to get down into 4" bore
1343						- Into 4" and set @ 90'
1350						- Hung up again going down to 110' around 103'
1410						- Tool set @ interval depth * Bottom of top gland at 148' * Doing one more pumptest before starting our packed off interval file
1415						- Sucessful pump test @ .25gpm (15,15) cycle
1418						- stopped decent log
1423						- started interval 148'-168' log
~~1223~~						*
						- Packer inflation calculations
	1)	* 700 psi max based on hole size table				
	2)	* Max water pressure above lower packer is 52.7 psi				
	4)	* 1.2 * 53 = 63.6 ≈ 64 psi is recomended minimum

Date 7-24-12
Page 1 of 7

Real Time	Depth to Water	Gauge 1 Flow	Gauge 1 Total	Gauge 2 Flow	Gauge 2 Total	Elapsed Time/comments
0640		- Depart hotel				
0702		- Arrive onsite for H+S meeting				
0740		- On MW-72BR-200 / Begin setup for the day				
0755		- Tool power on / Prepacing to log an ascent file from 148' to 109.5'				
0805	57.95'					
0815		- Begin Ascent from 148' to 109.5'				
		- Lower PT 53 psi @ start (32'-8.25' = 23.75' below d				
		* 53 psi / .433 = 122.4ft				
		* 148' + 23.75' = 171.75'				
		* 171.75' - 57.95' = 113.8'				
		* @ surface about 2.9 psi offset				
		* 113.8' + (2.9/.433) = 120.5'				
		- Lower PT 40.6 psi				
		* 40.6 psi / .433 = 93.76'				
		* 119.97' + 23.75' = 143.72'				
		* 143.72' - 57.95' = 85.77'				
		* 2.9 psi offset				
		* 85.77' + (2.9/.433) = 92.47'				
		* 93.76' - 92.47' = 1.29' offset (too high)				
		* Actual depth: 119.97' - 1.29' = 118.68'

Page 2 of 7

Real Time	Depth to Water	Gauge 1 Flow	Gauge 1 Total	Gauge 2 Flow	Gauge 2 Total	Elapsed Time/comments
		- Upper PT 28.9 psi				
		* 28.9 psi 1.433 = 66.74				
0910		- Tape measure shows 107.15' bottom of hole				
		- Tape measure → 109.4' probable top of tool				
		-				
0925		- Lowering packer to 109.5' (SRT)				
0932		* Based on measurements and discussion with WHP we are setting packer @ 109.5' to see if we can isolate top flow zone.				
		* Being recorded in the Ascent from 148' File				
		- Lower PT @ 36.1 psi				
		* 36.1 psi / 1.433 = 83.37'				
		* 109.5' + 23.75' = 133.25'				
		* 133.25' - 57.9' = 75.35'				
		* 2.9 psi offset				
		* 75.35' + (2.9/.433) = 82.05'				
		* offset: 83.37' - 82.05' = 1.32'				
		* Actual: 109.5' - 1.32' = 108.18'				
0936		- Begin inflating packer for seal test (109.5)				
		* No Seal				
0939		- Deflating packer & lowering 6"				
		-				
0942		- Inflating packer to check for seal (110')				
		* After packer inflation no pressure change (no seal)				
0951		- Lowering another 6"

DATA AND ANALYSIS

WELL MW72-BR-200
Topock, CA
CH2MHill - NorthStar

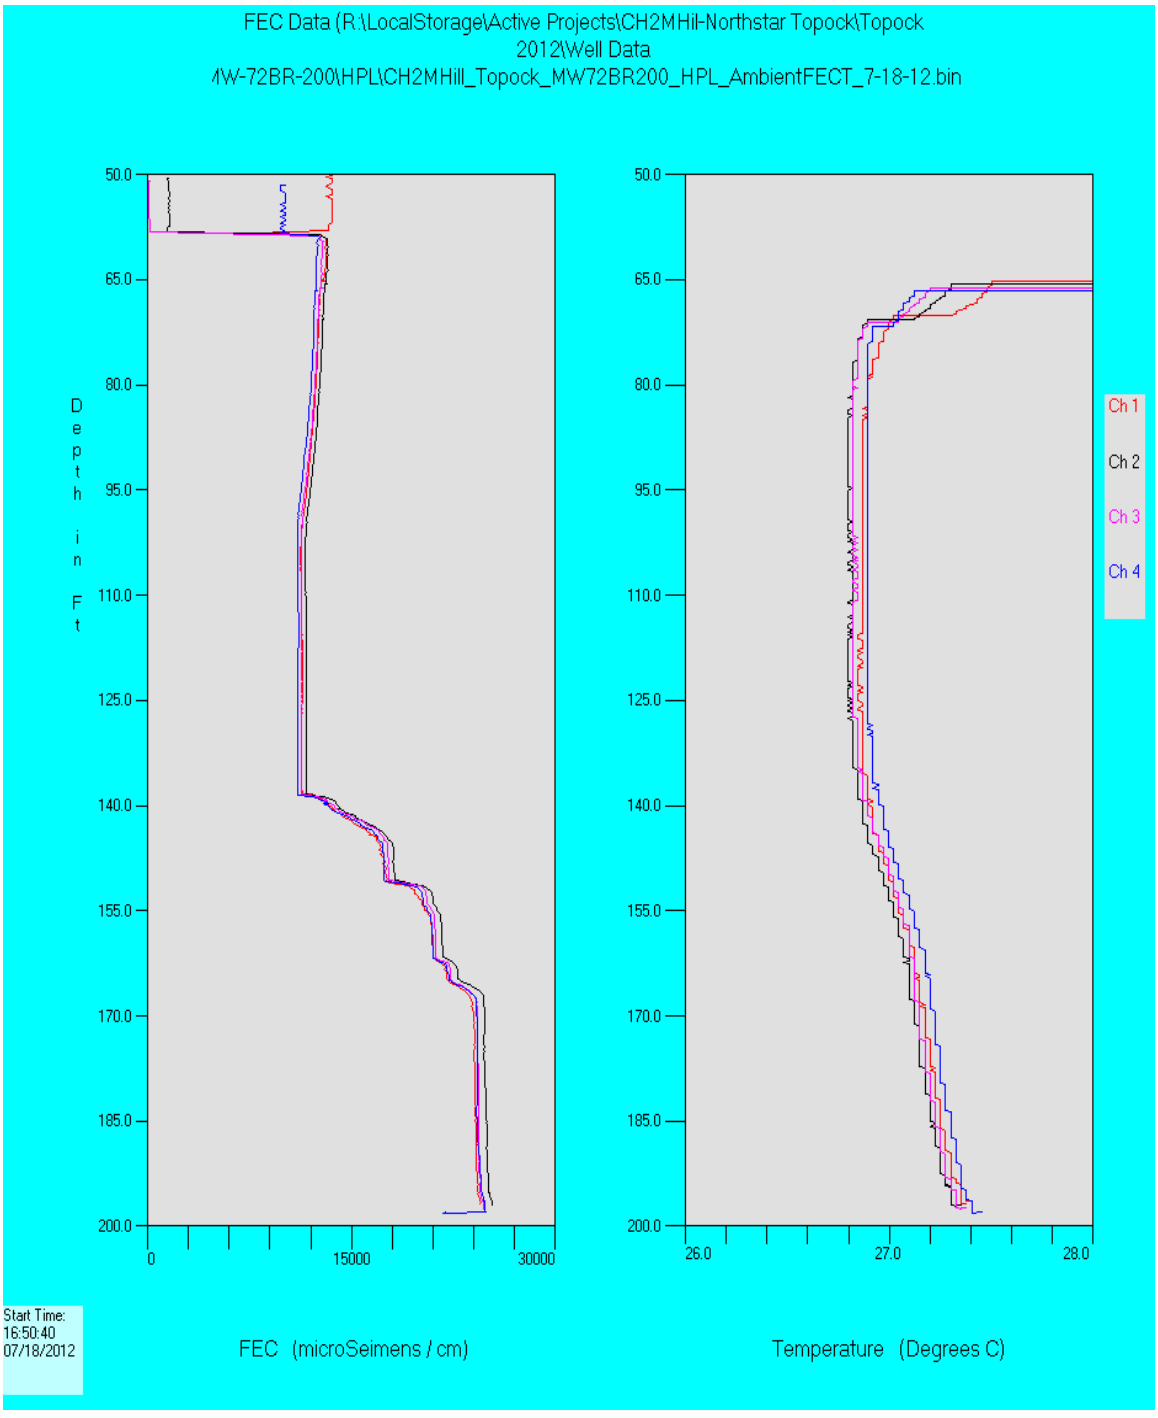

Figure 1. CH2MHill-Northstar, Topock - Well MW-72BR-200. Ambient FEC and Temperature log, July 18, 2012. Depth to water is 58.35 feet bgs. Log collected from within the temporary well screen, prior to removal. Bottom of 6 inch PVC conductor casing at105 feet bgs, temporary well screen from surface to 198 feet.

RAS

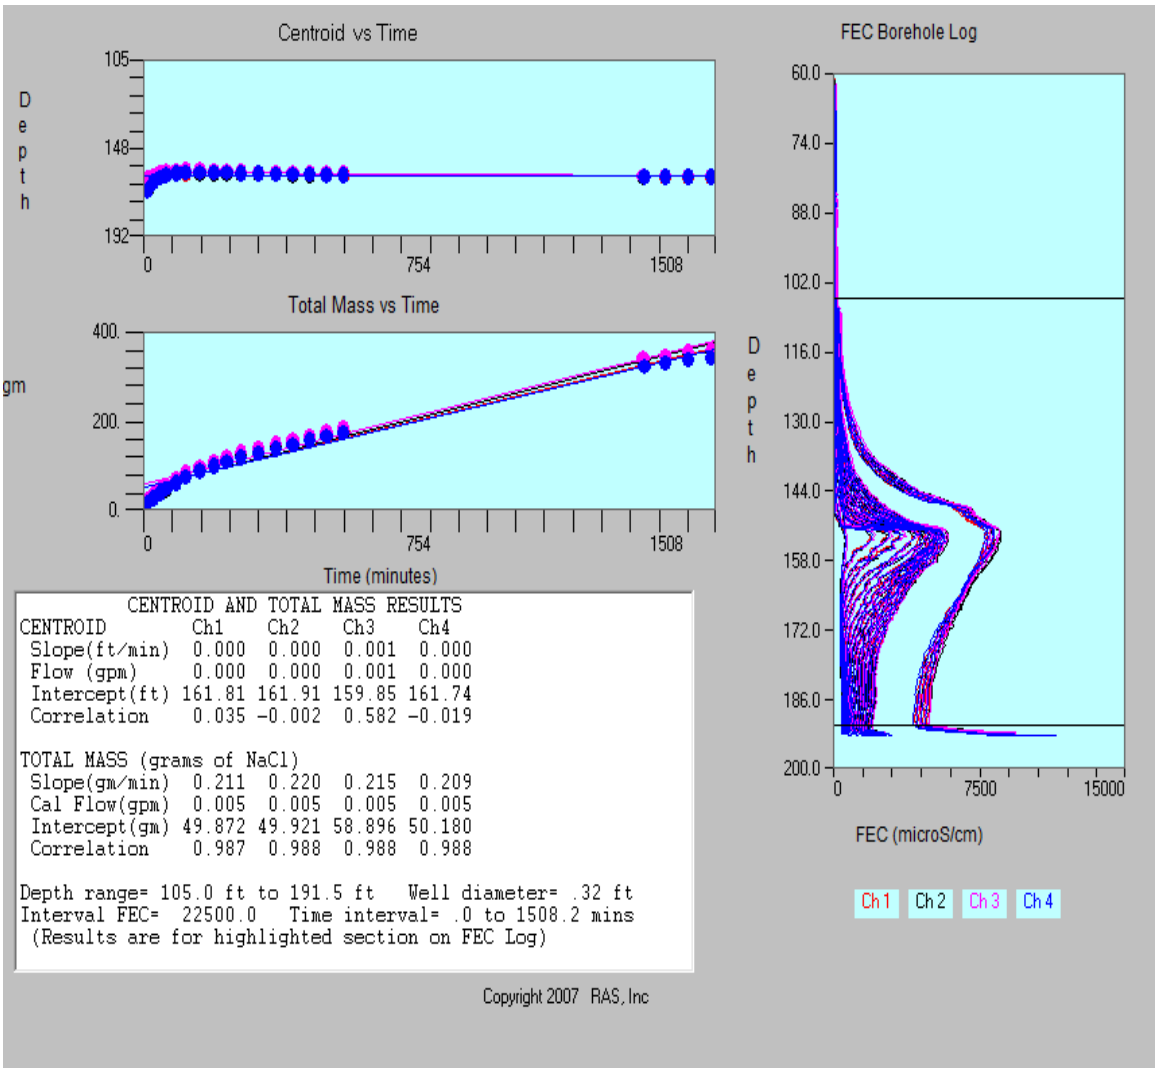

Figure 7. CH2MHill-Northstar, Topock - Well MW-72BR-200. Analysis of AFC logs Days 1 and 2 combined, July 20 and 21, 2012. Complete time interval shown. Interval FEC Value 22,500. Dominant inflow at 153 feet bgs is less than 50% saturation after less than 24 hours of recovery. Note that the logging interval lower limit was 191.5 feet and was insufficient to quantify inflow below this depth. As such, inflow from 191.5 to 198 (TD) was estimated.

Integrated Subsurface Evaluation
311 Rock Avenue • Golden, CO 80401
PH 303.526.4432 • FAX 303.526.4426
www.rasinc.org • bpedler@rasinc.org

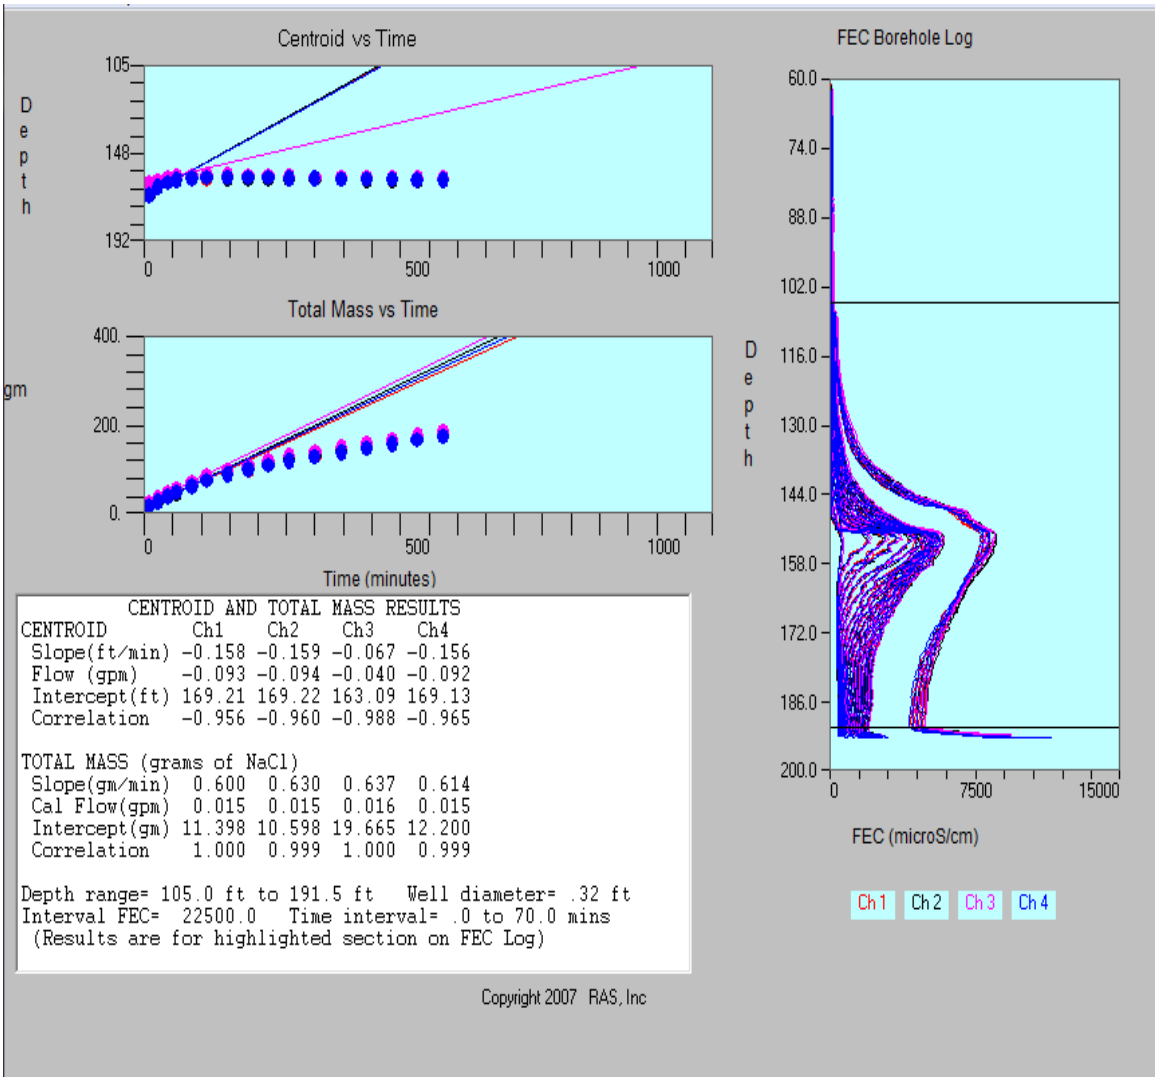

Figure 8. CH2MHill-Northstar, Topock - Well MW-72BR-200. Analysis of AFC logs Days 1 and 2 combined, July 20 and 21, 2012. Early logs only - time interval 0 to 70 minutes shown. Interval FEC Value 22,500. Total interval inflow = 0.015 gpm, not including flow form the bottom interval below 191.5 feet.

Integrated Subsurface Evaluation
311 Rock Avenue • Golden, CO 80401

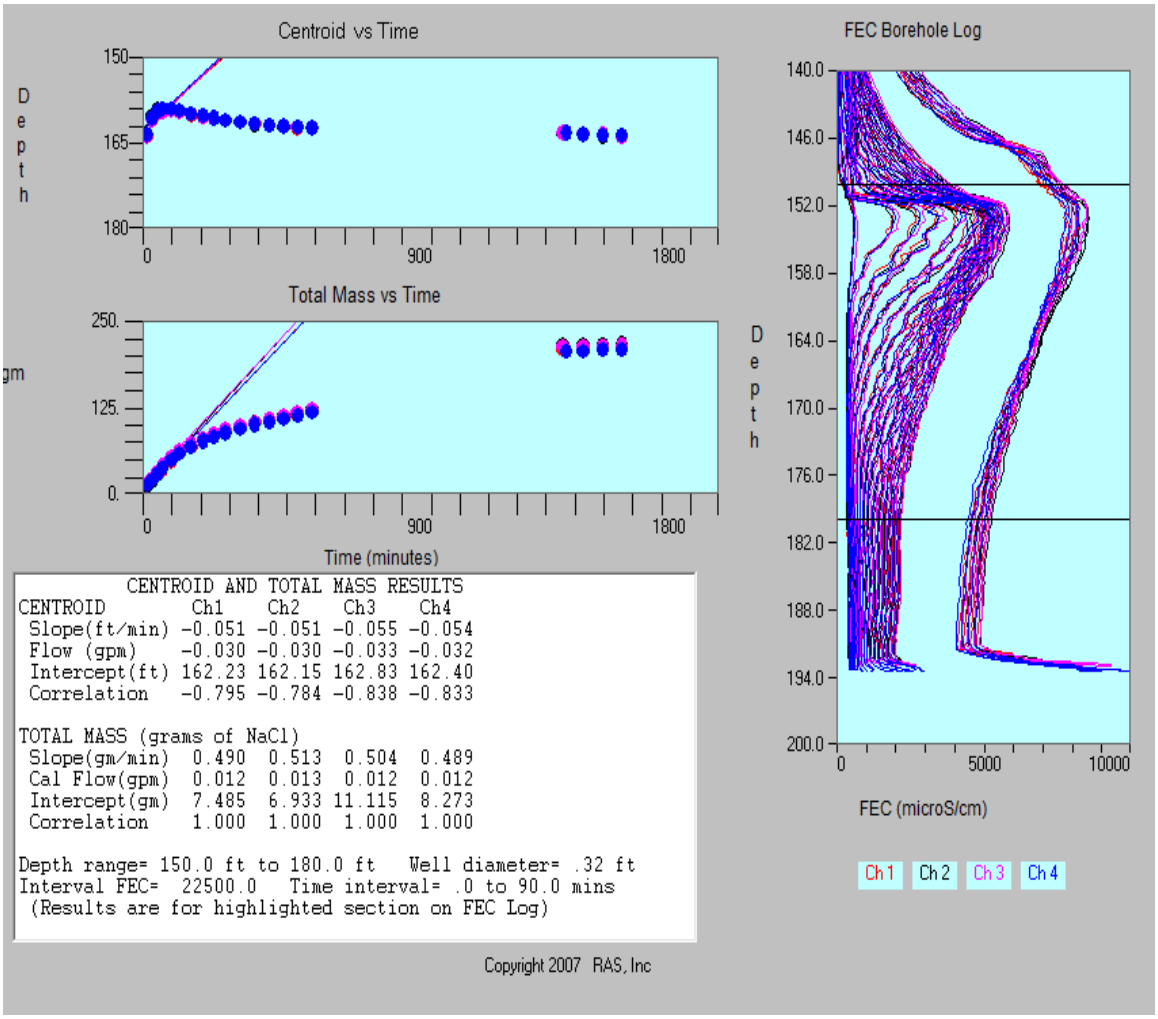

Figure 10. CH2MHill-Northstar, Topock - Well MW-72BR-200. Analysis of AFC logs Days 1 and 2 combined, July 20 and 21, 2012. Early logs only - time interval 0 to 90 minutes shown. Interval FEC Value 22,500. Total interval inflow = 0.012 gpm. Analysis of early logs suggests a dominant inflow interval of between 151 and 156 feet bgs. Analysis of QC flow data suggests other secondary features between 147 and 149 feet bgs and also between 161 and 167 feet bgs.

LEGEND

LITHOLOGY

- Alluvium
- Bedrock, Metadiorite
- Fracture / Fracture Zone*

* Generic symbol does not indicate fracture orientation

HYDROPHYSICAL LOGGING AND RESULTS:

Fluid Resistivity and Fluid Temperature
Log performed during ambient conditions

AFC Interval Specific Flow
Flow recorded during Ambient Flow Characterization (AFC)

PDI Total, Incremental & Interval Specific Flow
Flow recorded while Pumping During Injection (PDI)

Horizontal flow observed during ambient conditions, inflows also evaluated during stressed (constant pumping) conditions. Horizontal flow rates based on integral method for q (Lowe, et. al., 1989) and dilution method for v (Drost, 1968).

Hydraulic conductivity estimates based on Hvorslev (1962), (Pedler, et al. 1988). Flow and velocity estimates based on hydrophysical logging results only.

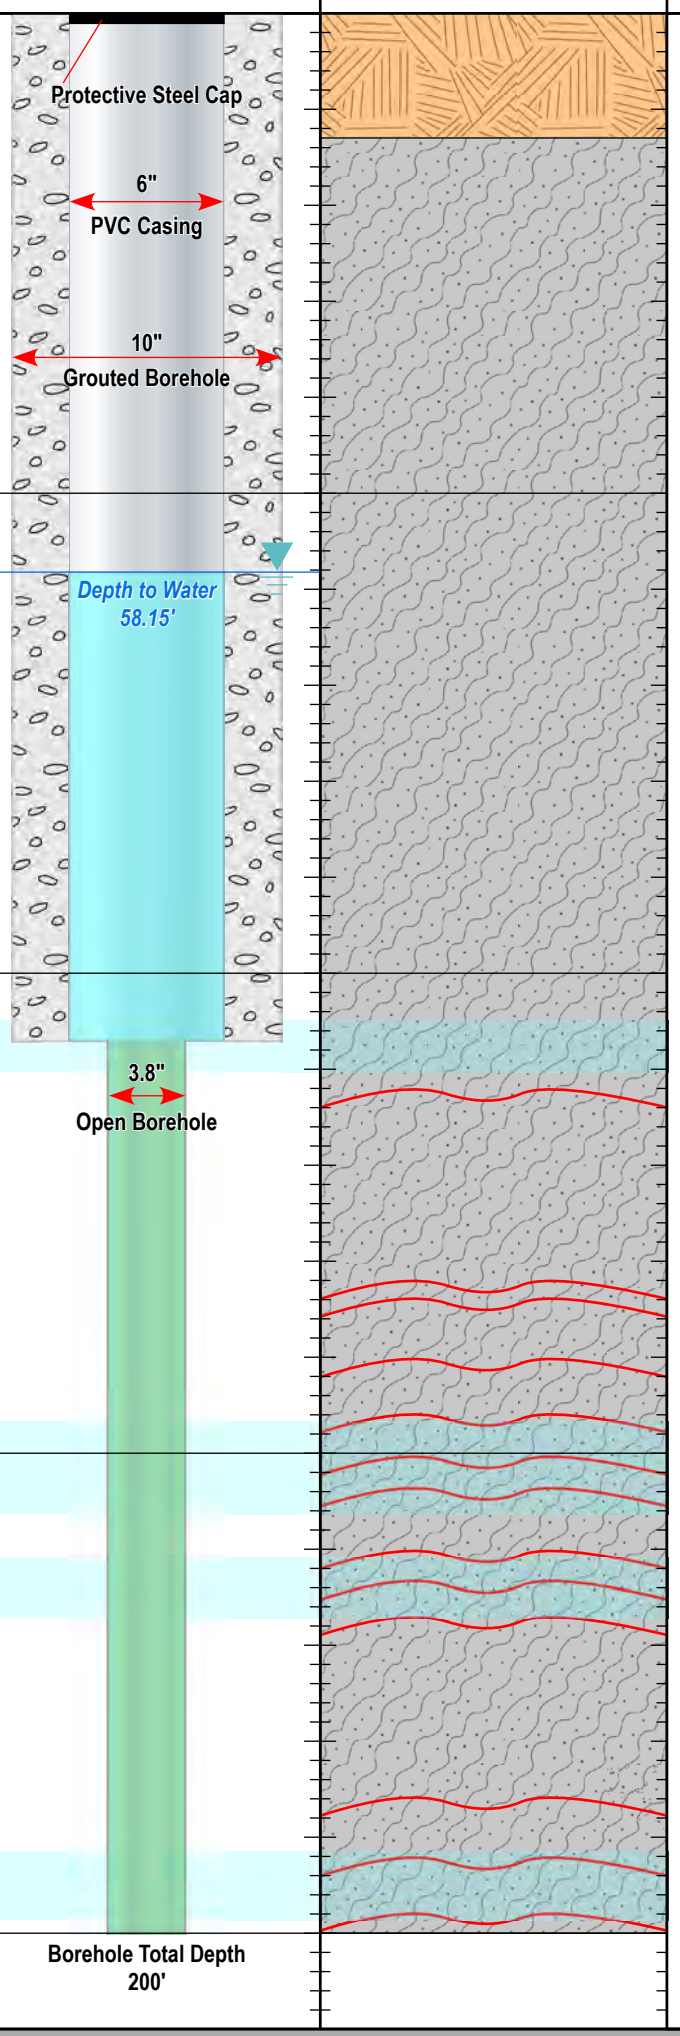
Flow Zones

HEXAVALENT CHROMIUM EXPLANATION

Hexavalent Chromium - Cr(VI) (µg/L)

Contaminant concentrations based on samples collected with the interval isolated via wireline straddle packer and collected via bladder pump.

MISCELLANEOUS NOTES:



1. Top of casing elevation: Not Surveyed.
2. All depths referenced to Ground Surface.
3. Coordinates of well: Not Surveyed.
4. Lithology and well construction from CH2MHill.
5. Hydrophysical logging conducted by RAS, Inc. on July 19, 20, 21 & 22, 2012 .

Integrated Subsurface Evaluation

September 22, 2009

Mr. Rob Tweidt
Northstar Environmental Remediation
26225 Enterprise Court
Lake Forest, California 96230

RE: **Hydrophysical Logging and Discrete Point Sampling Investigation, PG&E Topock Compressor Station, Needles, California**

Dear Mr. Tweidt:

Attached please find RAS's Final Report presenting results from our Hydrophysical Logging and Discrete Point Sampling Investigation at the PG&E Topock Compressor Station, Needles, California. The wells tested included MW-57BR, MW-58BR (after deepening), MW-62BR and MW-64BR,

We appreciate the opportunity to work with you on this project.

Please call with any questions.

Best Regards,
RAS, Inc.

William H. Pedler
President

Executive Summary

During the period from February 25 through May 8, 2004, RAS conducted borehole hydrophysics in four wellbores at the PG&E Topock Compressor Station in Needles, California. This work was performed for Northstar Environmental Remediation of Lake Forest, CA (Northstar) under contract to CH2MHill of San Francisco, CA, in support of their contaminant migration investigation. The objective of this work was to employ borehole hydrophysical and discrete point sampling methods to provide additional data for evaluation of the groundwater contaminant plume and to evaluate preferential groundwater migration pathways at the subject site.

RAS applied hydrophysical logging (HPL), and discrete point sampling methods to evaluate four newly drilled wellbores. These wells were MW-57BR, MW-58BR, MW-62BR and MW-64BR. Well MW-58BR was tested twice, the second time after additional drilling was conducted to deepen the interval of investigation. Details of testing procedures can be founded in Appendix A of this report. Detailed field notes describing field activities are included in Appendix B, data logs and results of analysis are included in Appendix C and integrated data montages for each well can be found in Appendix D. A CD-ROM data disk with all these data and a copy of this report is also attached.

Ambient flow characterization (native flow during ambient or background pressures conditions) was conducted in each well. In all wells, ambient flow was observed to be occurring at extremely low flow rates during the period of our testing. Interval specific ambient flow ranged from less than 0.001 to 0.005 gallons per minute (gpm). The lowest ambient flow was observed in well MW-64BR, where flow over the entire saturated interval (apparently via primary porosity or extensive annealed micro-fracturing) occurred at less than 0.001 gallons per minute (gpm). The highest ambient flow rate was observed in Well MW-57BR at 0.005 gpm at the interval from 168 to 174 feet[1] (ftbtopvcc).

Flow evaluation was also conducted during stressed conditions where flow was induced into the wellbore by either pumping or slug testing methods. Aquifer conditions permitted constant rate pumping to be conducted in three of the four wells (MW-57BR, MW-58BR and MW-62BR). Aquifer conditions at MW-64BR were such that low rate pumping (<0.5 gpm) could not be sustained and as such, slug test procedures were required. The results of this testing suggested that, in general, the water bearing intervals were moderate to extremely low flowing units with interval specific flow rates ranging from 0.008 to 2.20 gpm. The lowest interval specific flow rate occurred over the entire saturated portion of well MW-

[1] All depths are referenced to feet below top of PVC casing (ftbtopvcc) or feet below ground surface (ftbgs). The data montages presented in Appendix D include a column of depth referenced to MSL.

64BR (0.008 gpm) and the greatest interval specific flow rate occurred in Well MW-57BR at a depth of 168 to 174 ftbtopvcc at 2.10 gpm. It should be noted that the interval of highest flow during pumping also corresponded to the interval displaying the greatest ambient flow (MW-57BR).

Discrete point sampling was conducted in each well to evaluate the interval specific concentration and vertical distribution of hexavalent chromium in each well. For each well, the depth location for the discrete point sampling was based on the hydrophysical logging results. This type of sampling was employed because borehole conditions required installation of a temporary slotted screen casing. The condition of the geologic material encountered at each of the subjects wells was deemed sufficiently unstable that there was a real threat of borehole collapse. The installation of the slotted screen prevented unstable geologic materials from entering the well and provided a safe downhole environment for testing.

The results of the discrete point sampling were incorporated with the interval specific flow results in order to estimate the interval specific concentrations. These calculations are based on the mass balance equation. The observed concentrations (those concentrations reported from the laboratory) and the calculated interval specific concentration are presented on each well montage in Appendix D. Observed concentrations varied from ND or <1ppb (collected at 203 ftbtopvcc in well MW-58BR during ambient flow conditions) to 1200ppb (two samples collected at 94.5 and 108 ftbtopvcc both in well MW-62BR). The calculated interval specific concentrations ranged from ND or <1ppb.

Based on pressure histories and corresponding interval specific flow rates observed during ambient and pumping conditions, interval specific hydraulic conductivities were estimated for each well. These estimates were intended to be preliminary in nature and were not based on any site specific algorithms that may have been developed by others. For simplicity, the estimates were based on Thiem (1906) and presented in the summary table for each well. These results were also plotted on data montages in Appendix D. In summary, the resulting interval specific hydraulic conductivity estimates ranged from 6.4E-2 to 8.09E0 feet per day.

Based on geologic logs, collected by others and presented in the data montages, the subject wells encountered a layer of unconsolidated sediment overlaying either conglomerate or metadiorite bedrock water. However, in the case of MW-57BR, both types of bedrock were encountered with the conglomerate overlying the metadiorite. The highest interval of hydraulic conductivity was found in metadiorite in MW-57BR. In general, both geologic units contained water bearing intervals and neither was significantly more hydraulically conductive than the other.

A figure of interval specific hydraulic conductivity and corresponding chromium concentrations is presented in Figure 1. Due to the apparent lack of linear correlation between contaminant concentrations and hydraulic conductivities, fractures may still be the dominant mechanism for contaminant transport.

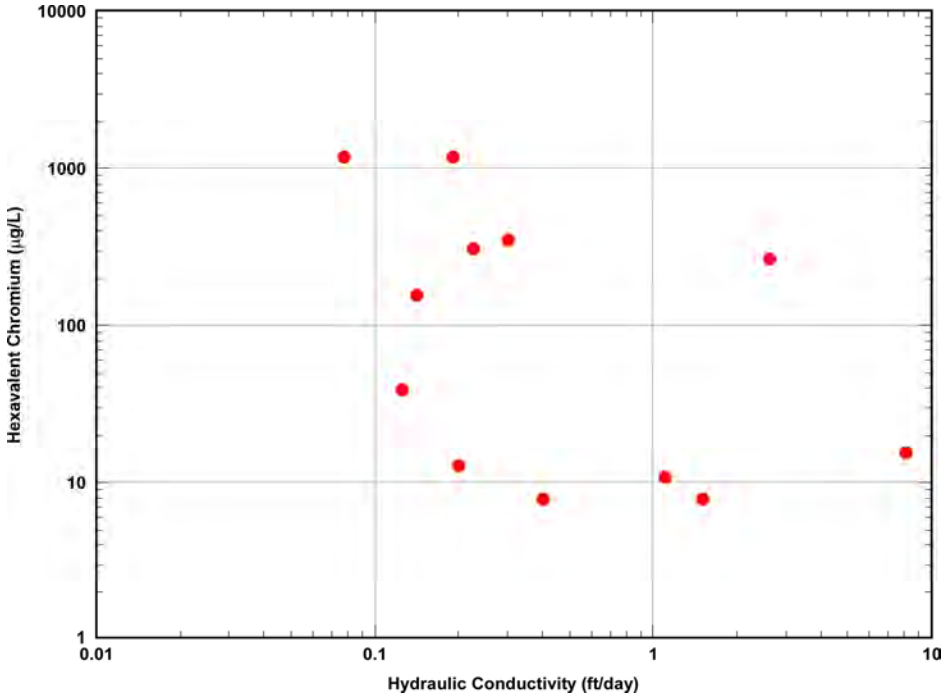

Figure 1. Interval Specific Hydraulic Conductivity versus Hexavalent Chromium.

Individual Well Discussion

On a well-specific basis, the RAS investigation suggested the following:

Well MW-57BR

During the period from February 26, 2009 to March 1, 2009, RAS conducted hydrophysical logging in well MW-57BR. The well had been recently drilled, properly developed and allowed sufficient time to stabilize prior to our arrival on site (greater than seven days). After conducting a health and safety meeting and being thoroughly briefed on site specific operational requirements, RAS personnel, under the direction and with assistance of Northstar, initiated equipment set up and check out. These procedures included initial decontamination of all downhole equipment, equipment move-in and configuration at the subject well. Test procedures, detailed notes of field activities and results of analyses can be found in Appendices A, B and C, respectively. The data montage for well MW-57BR with summarized results can be found in Appendix D. In addition, the final well construction and geology are included in this montage. This montage is the cornerstone of the following discussion of our results and is intended to be read together with this report.

The ambient FEC and temperature log is presented in panel nine of the MW-57BR data montage. The FEC log displays two distinct step change increases in FEC with depth. These step changes occurred from 117 to 130 and 145.5 to 156 ftbtopvcc. The temperature log displays a typical geothermal gradient with no discerning features of note. The temperature increased from about 25 to 28 degrees Centigrade (C) over the saturated interval of 56.5 to 177 feet. This equates to a thermal gradient of about 2.5 C per 100 feet.

Ambient flow characterization (AFC) was conducted on February 27, 2009. Please refer to Appendix A for detailed procedures of the test. At the time of testing, the depth to water was 53.09 ftbtopvcc. Flow characterization was conducted during the period from 12:50 to 17:40 hours, during which period, fourteen logging runs were conducted. Water level returned to within 0.1 feet of the background value after about 30 minutes. A final log was collected the following morning prior to commencing additional testing. Analysis of these logs using the centroid and integral methods suggest the presence of two water bearing intervals from 146 to 151 and 168 to 174 feet[2]. Ambient flow for these intervals was extremely low at 0.003 and 0.005 gpm, respectively.

On February 28, 2009, evaluation of these intervals by pumping during injection testing was conducted with a formation production rate of about 2.1 gpm. Analysis of the data collected during this testing suggested that the upper interval,

[2] All depths referenced to top of PVC casing.

from 146 to 151 ft was inflowing at 0.03 gpm and the lower interval from 168 to 174 was flowing at 2.1 gpm. These interval specific flow rates, with an associated drawdown of about 10.3 feet, resulted in interval specific hydraulic conductivity for the intervals at 146 to 151 and 168 to 174 ft of 1.25E-1 and 8.1E+0 ft/day, respectively. The HPL results also suggested that the upper and deeper flow intervals had interval specific FEC of about 2500 µS/cm and 20,000 µS/cm, respectively. Please refer to Appendix B for HPL data analysis details and a summary table of these results.

Based on the results of the HPL, discrete point sampling was conducted during ambient and pumping conditions. These groundwater samples were collected to evaluate the interval specific concentrations of hexavalent chromium concentrations. Sampling was conducted at 92.6, 102.0, 114.0, 154.0 and 174.9 feet. The results of the discrete point sampling were incorporated with the interval specific flow results in order to estimate the interval specific concentrations. These calculations are based on the mass balance equation. The observed concentrations (those concentrations reported from the laboratory) and the calculated interval specific concentration are the montage in Appendix D. In summary, the calculated interval specific contaminant concentrations for the intervals from 146 to 151 and 168 to 174 ft were 39 and 16 ppb, respectively.

Review of the natural gamma and induction/resistivity data and comparison to the HPL results does not suggest an obvious relationship between the flow intervals and a geophysical response. The details from the geologic log do not correspond or account for the geophysical responses. The cross-over signatures of the medium and deep induction/resistivity logs near the flow interval at 168 to 174 feet suggest a thin bed response and perhaps have some relationship to the flow interval. However, without high resolution optical or acoustic data over this interval, the physical nature of the flow intervals is challenging to discern.

Well MW-58BR

During the period from March 3 to March 5, 2009, RAS conducted hydrophysical logging in well MW-58BR. The well had been recently drilled, properly developed and allowed sufficient time to stabilize prior to our arrival on site (greater than seven days). Prior to installation, all downhole equipment was decontaminated. Following decontamination procedures, equipment move-in and configuration at the subject well were conducted. After equipment set-up, check out and calibration, RAS initiated hydrophysical testing and downhole sampling at well MW-58BR. Test procedures, detailed notes of field activities and results of analyses can be found in Appendices A, B and C, respectively. Based on these results, the well was subsequently drilled deeper and re-tested. As the subsequent testing included the originally drilled interval, only the later testing will be discussed and present in this report.

On April 30, 2009, RAS returned to the subject well and tested MW-58BR after additional drilling to deepen the subject well was completed. The total depth of the original wellbore was about 110 feet and with an ambient depth to water of 67.74 feet. The total depth after re-drilling was approximately 206 feet with the ambient depth to water at 67.44. Again, the well was allowed sufficient time to stabilize prior to testing. Hydrophysical logging and discrete point sampling were conducted during the period from April 30 to May 3, 2009. The results are summarized in the data montage for MW-57BR found in Appendix D. In addition, the final well construction and geology are included in this montage. This montage is the cornerstone of the following discussion of our results and should be read together with this report.

The ambient FEC and temperature log is presented in panel six of the MW-58BR data montage. The FEC log displays two distinct step change increases in FEC with depth. These step changes occurred from 86 to 93 ft with a more gradual increase with depth from 160 to 186 ftbtopvcc. The temperature log displays a typical geothermal gradient with no discerning features of note. The temperature increased from about 28 to 29.3 degrees Centigrade (C) over the saturated interval of 98 to 207 feet. This equates to a thermal gradient of about 1.2 C per 100 feet.

Ambient flow characterization (AFC) was conducted May 1 through May 2, 2009. Two days were required for AFC given the extremely low flow that was observed. Please refer to Appendix A for detailed procedures of the test. During the period of testing, the depth to water was relatively stable and only varied from 67.06 to 67.11 ftbtopvcc. A detailed pressure history is provided in the attached Processing Notes. Flow characterization was concluded on the morning of May 3, when the final AFC log was collected prior to initiating pumping. During this period, twenty logging runs were conducted. Analysis of these logs using the centroid and integral methods suggest the presence of very low-rate upflow occurring from the bottommost water bearing interval from 190 to 207 ftbtopvcc. Analysis of these data suggests that the inflow rate for this interval was extremely low at 0.004 gpm. The outflow location(s) could not be determined from these data due to the extremely low inflow rate and the extended period of additional testing time required (approximately five additional days).

On May 3, 2009, additional aquifer evaluation by slug test (rising head) after DI water emplacement testing was conducted with a water level head displacement of about 7 feet. The average formation production rate during logging was about 0.5 gpm. Analysis of the data collected during this testing suggested that seven (7) conductive, or water bearing, intervals were present. These intervals were at the depths of 95.9 to 103.7, 106.6 to 111.3, 114.7 to 120.1, 128.0 to 130.5, 132.4 to 136.3, 148 to 190 and 190.0 to 207 ftbtopvcc. The interval specific flow rates ranged from 0.003 to 0.27 gpm. The minimum and maximum inflow rates occurred at 128.0 to 130.5 and 148 to 190 ftbtopvcc, respectively. These interval specific flow rates, with an associated drawdown of about 6.8 feet, resulted in interval specific hydraulic conductivity estimates ranging from 0.2 to 2.6 feet per

day. The HPL results also suggested that the flow intervals had reasonably similar interval specific FEC of about 10,000 µS/cm. Please refer to Appendix B for HPL data analysis details and a summary table of these results.

On May 8, 2009, discrete point sampling was conducted during ambient and pumping conditions. These groundwater samples were collected to evaluate the interval specific concentrations of hexavalent chromium. Sampling during pumping at approximately 0.5 gpm was conducted at 125, 140 180 and 206 ftbtopvcc. Prior to initiating pumping, a sample was collected from 203 ftbtopvcc under ambient, upflowing, conditions. The results from the lab of the discrete point samples collected during pumping were incorporated with the interval specific flow results to estimate the actual interval specific concentrations, as based on the mass balance equation. The observed concentrations (those concentrations reported from the laboratory) and the calculated interval specific concentrations are presented on the montage for MW-57BR in Appendix D. In summary, the calculated interval specific contaminant concentration increased dramatically with depth, from 8 ppb for the conductive intervals at 95.9 to 103.7, 106.6 to 111.3, and 114.7 to 120.1 ft to 256ppb for the bottommost interval at 190.0 to 207 ft. However, the sample collected during ambient conditions was reported at <1ppb. This observation suggests that while this interval was uncontaminated during ambient pressure and flow conditions, after several hours of pumping, contaminated groundwater was drawn either vertically and or horizontally to the deepest interval in the subject well.

Limited geophysical data were available for comparison with the hydrophysical results. The interval over which the natural gamma and induction/resistivity data is available for comparison was 0 to 110 ftbtopvcc. This depth corresponds to the original depth of well MW-58BR prior to re-drilling. The uppermost water bearing interval occurs within this interval, from 95.9 to 103.7 ft. This water bearing interval encapsulates an increase in deep and medium resistivity. A decrease in natural gamma is also noted over this interval.

The details from the geologic log do not correspond or account for the geophysical responses. The cross-over signatures of the medium and deep induction/resistivity logs near the flow interval at 69 to 95 feet occurs in the meta-diorite and suggest either a variation in petrology, fracturing, fracture fill material, a combination of these factors or something else. Without high resolution optical or acoustic data over this interval, the physical nature of the flow intervals is very challenging to discern.

Please refer to Appendix B for HPL data analysis details and a summary table of these results.

MW-62BR

During the period from May 5 to May 8, 2009, RAS conducted hydrophysical logging in well MW-62BR. The well had been recently drilled, properly developed and allowed sufficient time to stabilize prior to our arrival on site (greater than seven days). Prior to installation, all downhole equipment was decontaminated. Following decontamination procedures, equipment move-in and configuration at the subject well were conducted. After equipment set-up, check out and calibration, RAS initiated hydrophysical testing and downhole sampling. Test procedures, detailed notes of field activities and results of analyses can be found in Appendices A, B and C, respectively.

On May 5, 2009, after tool calibration and an ambient FEC and temperature log hydrophysical logging for ambient flow characterization (AFC) was initiated. Ambient flow characterization was initiated on May 5 and conducted for two days due to extremely low inflow rates observed. Following AFC, flow characterization during stressed (pumping) and discrete point sampling were conducted from May 7 to May 8, 2009. The results are summarized in the data montage for MW-62BRfound in Appendix D. In addition, the final well construction and geology are included in this montage. This montage is the cornerstone of the following discussion of our results and should be read by the reader during his review of this report.

The ambient FEC and temperature log is presented in panel four of the MW-62BR data montage. The FEC log displays two distinct step change increases in FEC with depth. These step changes occurred from 88 to 99 ft with another at depth from 147 to 153 ftbtopvcc. The temperature log displays an atypical geothermal gradient with a distinct “swoosh” type signature. The temperature log was constant with depth at about 28.3 C to about 76.4 feet, and then the temperature gradually decreases to about 27.9 C at 139 feet, before resuming a traditional geothermal gradient to total depth (191 ftptopvcc).

Ambient flow characterization was initiated on May 5 and concluded the morning of May 7, 2009. This extended period of time was required given the extremely low flow that was observed. Please refer to Appendix A for detailed procedures of the test. After an initial stabilization period of about two hours following emplacement, the depth to water was relatively stable and varied only about 0.2 feet during the period of testing. A detailed pressure history is provided in the Processing Notes in Appendix B. Ambient flow characterization was concluded on the morning of May 7 when the final AFC log was collected prior to initiating pumping. During this period twenty logging runs were conducted. Analysis of these logs using the centroid and integral methods suggest the presence of a very low rate upflow occurring from the bottommost water bearing interval at 185 to 190 ftbtopvcc. Analysis of these data suggests that the inflow rate for this interval was extremely low at 0.01 gpm. The outflow location could not be unequivocally

determined from these data, but this analysis does suggests that the outflow zone was the uppermost water bearing interval from 85 to 95 feet.

On May 7, 2009, additional aquifer evaluation by pumping during deionized water injection was conducted. The average formation production rate during logging was 1.3 gpm with a reasonably stable drawdown of about 23.10 feet. Analysis of the data collected during this testing suggested that six (6) conductive, or water bearing, intervals were identified. These intervals were at depths 85.8 to 95.0, 95 to 107, 142 to 151.2, 156 to 171.2, 173.9 to 182.1 and 185 to total depth (~190) ftbtopvcc. The interval specific flow rates ranged from 0.04 to 0.56 gpm. The minimum and maximum inflow rates occurred at 142 to 151.2 and 185 to 190 ftbtopvcc, respectively. These interval specific flow rates, with an associated drawdown of about 23.1 feet, resulted in interval specific hydraulic conductivity estimates ranging from 4.45E-02 to 3.00E-01 feet per day. The HPL results also suggested that the flow intervals had increasing interval specific FEC with depth, specifically increasing from 6,000 at the uppermost interval to 12,200 µS/cm for the deepest water bearing interval. Please refer to Appendix B for HPL data analysis details and a summary table of these results.

On May 8, 2009, discrete point sampling was conducted during ambient and pumping conditions. These groundwater samples were collected to evaluate the interval specific concentrations of hexavalent chromium. Samples during pumping at approximately 1.2 gpm were collected from 94.5, 108, 149, 170, 184.5 feet and from the pump discharge. Prior to pumping, a sample was collected at 187 ftbtopvcc under ambient, upflowing, conditions. The results from the laboratory of the discrete point samples collected during pumping were incorporated with the interval specific flow results to estimate the actual interval specific concentrations, as based on the mass balance equation. The observed concentrations (those concentrations reported from the laboratory) and the calculated interval specific concentrations are presented on the well MW-62BR montage in Appendix D. In summary, the calculated interval specific contaminant concentrations notably decreased with depth, from 1200 ppb for the conductive intervals at 95.9 to 103.7, 106.6 to 111.3, 114.7 to 120.1 to 256ppb for the bottommost interval at 190.0 to 207 ft. However, the sample collected during ambient conditions was reported at <1ppb. This observation suggests that while this interval was uncontaminated during ambient pressure and flow conditions, after several hours of pumping, contaminated groundwater was drawn either vertically and/or horizontally to the subject well's deepest interval.

No geophysical data was available for comparison with the hydrophysical results.

Please refer to Appendix B for HPL data analysis details and a summary table of these results.

MW-64BR

During the period from May 27 to June 1, 2009, RAS conducted hydrophysical logging in well MW-64BR. The well had been recently drilled, properly developed and allowed sufficient time to stabilize prior to our arrival on site (greater than seven days). After conducting a health and safety meeting and being thoroughly briefed on site specific operational requirements, RAS personnel initiated equipment set up and check out. These procedures included initial decontamination of all downhole equipment, equipment move-in and configuration at the subject well. Downhole sampling was not conducted at well MW-64BR due to extremely low overall well yield and lack of any significant preferential flow intervals. Test procedures, detailed notes of field activities and results of analyses can be found in Appendices A, B and C, respectively. The results summarized the data montage for MW-64BR can be found in Appendix D. In addition, the final well construction and geology are included in this montage. This montage should be reviewed by the reader during his reading of this report.

The ambient FEC and temperature log is presented in panel four of MW-64BR data montage. The FEC log displays an increase in FEC with depth over the upper 40 feet of the fluid column. The temperature log displays a "swoosh" type signature, first decreasing to a depth 174 feet, then increasing to total depth. During the initial ambient FEC and temperature log, some residual drilling material was encountered at about 228 feet. This material fouled the FEC sensors causing the decrease in FEC at this depth and the remaining errant readings to TD. As such, the FEC data is not representative of the fluid column from 228 to 258 feet. This residual material was removed from the wellbore and all subsequent logs were successfully collected.

Ambient flow characterization was initiated on May 29, 2009. Please refer to Appendix A for detailed procedures of the test. At the time of testing, the depth to water was 119.48 ftbtopvcc. Ambient flow characterization was initiated May 29 at 12:05 and concluded on May 31 at 09:05 hours. During this period, fifteen (15) logging runs were conducted. At the completion of emplacement procedures, the water level was elevated approximately 6.5 feet above the ambient elevation. Hand bailing was conducted immediately after emplacement, and prior to logging, to carefully return the water level elevation back to the ambient elevation. Analysis of these logs using the centroid and integral methods suggest extremely low inflow over the entire saturated interval. No distinct or preferred flow intervals were apparent. As such, the observable and recorded increase in FEC suggests primary flow. Analysis suggests an inflow rate of less than 0.001 gpm for the entire saturated interval.

On May 31, 2009, flow evaluation of the saturated interval was conducted using the HPL slug test after emplacement (SAE) method. Analysis of the data collected during SAE testing supports the ambient flow characterization and confirms the lack of any preferential flow paths. Analysis of the data suggests

that the total flow over the entire saturated interval was 0.008 gpm. This overall flow rate is also supported by the water level recovery curve. Based on the rising head data, an overall hydraulic conductivity based on Hvorslev (1951) of 6.4E-2 feet per day was calculated.

The HPL results also suggested an interval specific formation water concentration of 11,000 µS/cm for the saturated interval. Please refer to Appendix B for HPL data analysis details and summary table of these results.

Based on the results of the HPL, discrete point sampling was not conducted as the well could not produce sufficient volumes of formation water without dewatering the interval(s) of interest.

Similar to MW-62BR, no geophysical logs were collected in this well.

Please refer to Appendix B for HPL data analysis details and a summary table of these results.

Limitations

Water levels have been measured in the well bores at the times and under the conditions stated in the report. These data have been reviewed and interpretations have been made in the text of this report. However, it must be noted that fluctuations in the level of the groundwater may occur due to variations in rainfall and other factors different from those prevailing at the time measurements were made.

Except as noted within the text of the report, no quantitative laboratory testing was performed to verify the calibration of the logging tool. Where such analyses have been conducted by an outside laboratory, RAS, Inc. has relied upon the data provided, and has not conducted an independent evaluation of the reliability of these data.

Conclusions and recommendations contained in this report may be based in part upon various types of chemical data and are contingent upon their validity. These data have been reviewed and interpretations made in the report. As indicated within the report, these data are developed based on the field calibration of the logging tool. Where more specific information is necessary, the tool measurements should be verified based on quantitative lab analyses of grab samples obtained directly from the wellbore. Moreover, it should be noted that the variations in the types and concentrations of groundwater constituents and variations in their flow paths may occur due to seasonal water table fluctuations, past site practices, the passage of time, and other factors. Should additional chemical data become available in the future, these data should be reviewed by RAS, and the conclusions and recommendations presented herein modified accordingly.

The values for bedrock hydraulic conductivity given in this report should be viewed as "equivalent hydraulic conductivities", which are computed based on an assumed, or equivalent, interval length and a uniformly pervious porous media behavior. This industry standard approach has several limitations, which are well documented in the current literature. In addition, the accuracy of the equivalent hydraulic conductivities when presented herein is subject to the applicability of the boundary condition assumptions inherent in the permeameter/slug test/pumping test analysis method used.

RAS's logging was performed in accordance with generally accepted industry practices involving similar studies at the same time and in the same general area. RAS has observed that degree of care and skill generally exercised by others under similar circumstances and conditions. Interpretation of logs from the newly developed techniques, Scanning Colloidal Borescope Flowmeter, Hydrophysical Logging ("NxHpL™") and Wireline Straddle Packer Testing ("WSP™") (whether made directly from visual observations or by data processing or otherwise), or

interpretation of test or other data, and any recommendation or hydrogeologic description based upon such interpretations, are opinions based upon inferences from measurements, empirical relationships and assumptions. These inferences and assumptions require engineering judgment, and therefore are not scientific certainties. As such, other professional engineers or analysts may differ as to their interpretation. Accordingly, RAS cannot and does not warrant the accuracy, correctness or completeness of any such interpretation, recommendation or hydrogeologic description.

All technical data, evaluations, analysis, reports, and other work products are instruments of RAS's professional services intended for one time use on this project. Any reuse of work product by Client for other than the purpose for which they were originally intended will be at Client's sole risk and without liability to RAS. RAS makes no warranties, either express or implied. Under no circumstances shall RAS or its employees be liable for consequential damages.

1.0 SCOPE

1.1 Purpose

The purpose of this procedure is to assure the accuracy, validity, and applicability of the methods used to record hydrophysical logs in a previously drilled borehole. This procedure provides a guide for the Client's contractor to perform the described activity. From this procedure the Client can evaluate these activities for meeting the requirements of the Project.

This procedure describes the components of Hydrophysical logging, the principles of the methods used and their limits. It also describes the detailed methods to be used for calibration, operation and performance verification of the equipment. In addition, requirements for data acceptance, documentation, and control are defined, and means of data traceability are provided.

1.2 Applicability

This procedure applies to all personnel contractor personnel who may perform work or use data obtained from this procedure if it is deemed to potentially affect public health and safety related the Project

2.5 Technical procedure TP-13.

3.0 DEFINITIONS

© 2008, RAS, Inc.

3.1 Hydrophysical Logging: Technology for evaluating hydrologic conditions surrounding a borehole.

Specifically, The Hydrophysical (HPL) logging method uses repeat logs of FEC and temperature to analyze and determine the location of hydraulically conductive intervals within a wellbore. The results can be used in conjunction with drawdown data obtained during active pumping to determine interval specific hydraulic conductivity or transmissivity. The technique can also be used to characterize ambient (non-pumping) flow conditions.

3.2 FEC: Fluid electrical conductivity.

3.3 Standard Reference Solution: A solution of known electrochemical properties, calibrated to a known FEC, to be used for calibration of HpL Sonde.

3.4 HPL Sonde: Wireline logging tool which measures FEC and temperature for use during Hydrophysical Logging.

3.6 Emplacement - The process of replacing ambient fluids in a borehole with deionized water.

3.7 Injection line - Either flexible tubing or rigid pipe used for emplacement.

3.8 Affected Interval: That interval in a borehole into which fluids flow during inflow or out of which fluids flow during outflow.

During ambient testing, the affected interval is defined as the zone between the deepest productive interval in a given well and the water surface.

During active pumping or DI emplacement, the affected interval is defined as the zone between the deepest hydraulically active interval in a given well and the inlet of the extraction pump.

3.9 Low yield well: Any well having a specific capacity less than 0.1 gallon per minute per foot of drawdown.

3.10 Moderate yield well: Any well having a specific capacity between 0.1 gallon per minute and 4.0 gallons/minute per foot of drawdown.

3.11 High yield well: Any well having a specific capacity greater than 4.0 gallons per minute per foot of drawdown.

3.12 Specific capacity is defined as the rate of fluid influx of a borehole, in units of flow rate per unit drawdown.

© 2008, RAS, Inc.

3.13 Slug test: Method for testing flow in a well which involves rapid extraction of a finite fluid volume to produce a one-time, sudden, finite decrease in fluid level in the well, and monitoring subsequent fluid recovery.

3.14 Pumping test: Method for testing flow in a well which involves continuous extraction of fluid at a constant rate to maintain a fixed decrease in fluid level in the well, while monitoring fluid extraction rate and water level. In HpL testing, a pumping test may also include simultaneous fluid injection at a fixed rate.

7.1 Deionized (DI) water: Water with a very low concentration of dissolved species and having typically between 5 and 25 µS/cm conductivity.

7.2 Discrete Point Fluid Sampler: Down hole logging tool that is used to collect a depth specific fluid sample lowered to a depth pre-selected by hydrophysical logging results.

3.17 Personnel

3.17.1 Principal Investigator (PI): Responsible for assuring full compliance with this procedure. PI shall require that all personnel assigned to work under this procedure have the necessary technical training, experience, and personnel skills to adequately perform this procedure.

The PI is also responsible for overall operations and data quality.

The PI shall determine whether the data and procedures meet the acceptance criteria.

3.17.2 If necessary due to field conditions, the PI may perform the duties of the Logging Engineer and/or the Technician.

3.17.3 If necessary due to field conditions, the Logging Engineer may perform the duties of the Technician.

4.0 REQUIREMENTS

4.1 Prerequisites

4.1.1 Borehole of appropriate size and completion methodology.

In open bedrock boreholes, casing shall be installed through the overburden and grouted at the rock/alluvium interface to inhibit water leakage into the borehole from the saturated alluvium. For cased boreholes, the well shall be fully cased and gravel packed with single or multiple screened intervals.

© 2008, RAS, Inc.

The diameter of the borehole shall be 4 inches or greater. For boreholes which require higher pumping rates (> 4 gpm) a 4 inch diameter pump may be required. For use with a 4 inch diameter pump, the diameter of the borehole shall be 6 inches or greater.

For newly drilled wells, cuttings and drill fluids shall be removed from the affected fractures by standard well development procedures.

4.1.2 Source of DI water. If DI water is prepared at the site, the pre-treated water shall be potable and less than 1000 µS/cm FEC.

4.1.3 Surface injection and submersible extraction pump(s) for HPL testing.

4.2 Tools, Material, and Equipment

Typical field equipment includes for shallow (less than 300 feet total depth):

- Fluid management system
  - Back Pressure Regulator or orifices
  - Rubber hose (0.75-inch i.d.) for injection
  - Submersible Pump
  - Evacuation Line
  - Storage tanks (as required) with inlet/outlet valves
  - Surface Pump
  - Fluid management manifold/Monitoring Panel
  - Mechanical hose spoolers (pump, injection)
  - Data Acquisition System (for recording volumes, flow rates, time)
  - Wireline System
  - Cable
  - Power supply
    - Wireline winch unit
    - Boom and drawworks
  - Depth encoder
  - Water level indicator
  - Computer System
  - NxHpl™ Logging tool
  - Downhole Fluid Sampler

- Deionized water (prepared with wellbore fluids or transported on-site)
- Appropriate water sample containers (typically provided by client)
- Steam Cleaner (for logging/sampling tools)
- Deionizing Units

© 2008, RAS, Inc.

4.2.2 For wells greater than 300 feet total depth, an independent pumping system and standard wireline logging truck is required. This includes:

Wireline System, Cable, Power supply, Wireline winch unit, Boom and drawworks, Depth encoder, Water level indicator, Computer System, Hydrophysical Logging tool, and Downhole Fluid Sampler.

4.2.3 RAS independent pumping system includes:

Fluid management system, Back Pressure Regulator or orifices, 1" galvanized pipe for injection lines, 2" galvanized pipe for evacuation lines, Submersible Pump, Storage tanks (as required) with inlet/outlet valves, Surface Pump, Fluid management manifold/Monitoring Panel, and Data Acquisition System (for recording volumes, flow rates, time).

4.2.4 Deionized water (prepared with wellbore fluids or transported onto the site).

4.2.3 Standard reference solutions: A minimum of 4 prepared solutions for calibration check of FEC measurements by the HpL sonde.

4.2.4 Surface flow meters may be provided by the client.

4.2.5 Steam cleaning equipment, if required.

4.3 Precautions and Limits

7.1.1 The operational temperatures and pressures for the RAS's advanced, multi FEC/T arrayed hydrophysical tool are:

- Maximum operating pressure is approximately 1,000 PSI.
- Maximum practical operational temperature is 80^{o}C.

4.3.2 Hydrophysical tests require that the borehole fluid be emplaced with deionized water. Improper emplacement of the DI water or its subsequent contamination can drastically affect the quality of the test.

4.3.3 The minimum borehole size is 4". Larger boreholes (6" or greater) may be required to utilize 4" diameter pumps if it is necessary to achieve flow rates higher than approximately 4 gpm. This may occur when testing of a high yield well.

4.3.4 The Hydrophysical technique requires a fluid filled borehole.

© 2008, RAS, Inc.

7.1.1 Bridges, constrictions in the borehole diameter, will make it impossible to lower the tool into the borehole and difficult to retrieve the tool.

4.4 Acceptance Criteria

7.1.1 Forms shall be filled out as called for in this Technical Procedure.

7.1.2 Field calibration checks shall meet the criteria outlined in TP-13.

7.1.3 Evaluation of the test procedure and data for acceptability shall be the sole responsibility of the PI.

5.0 DETAILED PROCEDURE

When logging for hydrologic purposes only, as in this procedure, FEC and temperature measurements are sufficient to characterize the well.

5.1 Before Arrival On Site

5.1.1 Examine any previously obtained wireline logs, noting in particular conditions which may cause tool sticking or variations in data quality.

5.1.2 Note depths of water table, surface casing, hole size changes, and hole bottom for use in calibrating depth measurements during logging.

5.1.3 The PI shall discuss hole conditions with the drillers, or review drilling reports for information which may affect the design of the HpL tests.

5.1.4 The PI shall review recent field activities carried out in the borehole of interest which may impact hydrology or fluid chemistry within the interval affected by the HpL tests. This includes but is not limited to any pump tests, interference tests, or load tests.

5.1.5 The PI shall also review all pre-existing hydrogeological data from the site and develop a preliminary testing plan, based on all information which can allow determination of whether the well will be low, moderate, or high yield.

5.1.6 Evaluation water quality and determine if it is necessary to provide an external water source for DI water.

© 2008, RAS, Inc.

5.1.7 Prepare a list of materials requirements, including pump(s) if necessary, tubing, measurement equipment, and the necessity to provide a source of DI water.

5.1.8 Each measurement device which affects quality shall be calibrated prior to use.

5.2 Upon Arrival On-Site

In addition to the requirements of TP-13:

5.2.1 The well site shall be clear of all equipment within a 25 foot radius of the well head.

5.2.2 Calibration documents for all quality affecting measurement devices shall be made available to the site manager upon request.

5.3 Verify on site conditions

5.3.1 Review well construction details and record available site conditions, well conditions and flow yield information, verify the previously designed testing program.

5.3.2 Review and record additional wellbore construction/site details recorde the following information:

Ambient depth-to-water, depth of casing, depth of well, lithology (if available), estimated well yield and any available drawdown data, and type and concentration of contamination (if any).

5.3.3 Prepare deionized (DI) water. Consult with DI water tank firm for assistance if necessary. If DI water has not been transported to the site, surface or groundwater may be used if it is of suitable quality. Generally, source water containing less than 1000 micro Siemens per centimeter (µS/cm) and less then 20 ppb VOCs will not significantly affect the deionizing units, but this should be confirmed with the DI water firm. If the groundwater from the well under test cannot be used for DI water generation, then DI water must be transported to the site and containerized at the wellhead.

Depending on the amount of Hydrophysical testing to be performed (ambient and/or active) the typical volume of DI water required for each borehole is approximately three times the volume of the standing column of formation water in the wellbore per type of Hydrophysical characterization.

© 2008, RAS, Inc.

If preparation takes place on site, pump the source water through a pre-filter, to deionizing units, and into the storage tanks.

Monitor the FEC of the DI water in-line to verify homogeneity; the target value is 5 to 25 µS/cm. Record the results.

5.3.4 A pre-survey calibration check of the HPL sonde shall be performed.

5.4 Conduct ambient FEC/Temperature log

5.4.1 Set datum on the depth encoder with the FEC sensor on the tool as 0 depth at the top of casing. If no space is available at the wellhead, measure 10 feet from the FEC sensor up the cable (using measuring tape) and reference with a wrap of electrical tape. Lower the tool down the hole to the point where the tape equals the elevation at the top of the casing and reference that as 10 feet depth on the depth encoder.

5.4.2 Place the top of the tool approximately 3 feet below the free-water surface to allow it to achieve thermal equilibrium. Monitor the temperature output until thermal stabilization is observed at approximately ± 0.2 °C. The rate of change of temperature shall be less than 1 °C/minute.

5.4.3 After thermal stabilization of the logging tool is observed, log the ambient conditions of the wellbore (temperature and FEC). During the logging run, the data shall be plotted in real time in log format on the computer screen and the data string shall be simultaneously recorded on the hard drive.

Log the ambient fluid conditions in both directions (i.e. record down and up). The ideal logging speed is 5 feet per minute (fpm).

5.4.4 At the completion of the ambient FEC/Temperature test, the recorded data shall be backed up *immediately* to floppy disk (high density disk) or CD-R.

At completion of the ambient log, place the tool approximately 10 feet below the free water surface. The tool may remain there during equipment set up as long as borehole conditions permit. The Logging Engineer under PI direction may choose to remove the logging tool from the well during installation of the pumping equipment.

5.4.5 Measure and record ambient depth.

5.5 Conduct ambient flow characterization

© 2008, RAS, Inc.

Ambient flow characterization consists of a time series of FEC logs recorded after DI water emplacement. Continuous logging of the interval of interest is required. In addition to the logging results, pressure and flow data shall be recorded throughout the test in digital form and periodically in field notes.

5.5.1 DI Emplacement Procedure.

DI water is injected at the bottom of the well. Water is extracted from the top to maintain a constant water level in the well, to minimize disturbance to the local hydrologic system. The HpL sonde is used during emplacement to monitor the position of the DI water front as it moves up the well. A pressure transducer placed immediately below the extraction pump is used to monitor the water level in the well.

5.5.1.1 Attach back pressure regulator or orifice, if used, and weighted boot, to end of emplacement line and secure. Insure that the injection line is of adequate length to reach the bottom of the wellbore.

5.5.1.2 Lower the flexible emplacement line to the bottom of the well allowing one foot of clearance from the well bottom to the outlet of the injection line.

5.5.1.3 Lower tool about 10 feet below the water surface. The tool will be stationed beneath the submersible pump during non-logging times.

5.5.1.4 Lower submersible pump in the well to a depth just above the logging tool. Record approximate depth of the pump location.

5.5.1.5 Lower a pressure transducer a minimum of 5 feet below the bottom of the pump.

(The sequence of 5.5.1.3 through 5.5.1.5 may be changed as required at the discretion of the PI or Logging Engineer.)

5.5.1.6 Record all initial readings of gauges at elapsed time 0.0 minutes.

5.5.1.7 Mark hoses with a round of electrical tape for reference. In addition, establish datum for tool depth to the nearest foot and mark on wire with wrap of tape. Reset datum on optical encoder for this depth.

© 2008, RAS, Inc.

5.5.1.8 Pump DI water to the bottom of the wellbore using the surface pump and the injection riser. Simultaneously use the submersible pump to maintain a stable, elevated total head by extracting groundwater from near the free water surface. The injection and extraction rates should be approximately the same. When groundwater from the subject well is used for DI water generation, generate DI water from the extracted formation water and recirculate to the well bottom via the solid riser.

5.5.1.9 Throughout this procedure, the water level and flow data shall be recorded digitally. In addition, a hand-held water level meter shall be used to periodically record the elevated total head. All flow data shall be periodically recorded to field notes.

5.5.1.10 Evaluate the rate at which the DI water advances up the well. In the event that it is necessary to modify the rate of injection/extraction, the PI shall oversee the change.

If borehole conditions permit (i.e. the absence of constricted borehole intervals), the logging tool is used to monitor the advancement of the fluid up the borehole as it displaces the standing formation water. Draw the logging tool up the wellbore in successive increments as the DI water is emplaced. The logged FEC value changes from that of the ambient fluid to that of DI water at the depth of the DI water interface. Continuous profiling may also be performed to monitor the progress of DI water emplacement.

5.5.1.11 Monitor and record the electrical conductivity of the fluid expelled from the extraction pump during emplacement procedures. Record these values and the times at which they were measured.

5.5.1.12 Emplacement is complete when DI water, or sufficiently diluted formation water, is observed from the evacuation pump or when logging tool stationed near the pump indicates DI water or sufficiently diluted formation water.

5.5.1.13 Upon completion, turn off the evacuation pump. Then turn off the injection line.

5.5.1.14 If a pumping rig is used, check valves shall be installed in the extraction line to ensure that fluid is not drawn back

© 2008, RAS, Inc.

into the well when the pump is turned off. In this case, leave the emplacement line, the extraction pump, the pressure transducer, and the HpL sonde in the well.

5.5.1.15 If appropriate, the extraction line shall be removed from the well immediately after emplacement is complete.

5.5.1.16 Record volumes of extracted and injected fluids. Calculate the volume of DI water lost to the formation: $V_{injected} - V_{extracted} = V_{lost}$. This value will be negative if there is a net flow into the well.

5.5.2 After DI emplacement is complete, perform continuous FEC/Temperature logging until 80% saturation is observed in the affected interval, or until 5 hours of logging has been performed.

5.6 Characterize the well for additional testing

The RAS PI shall determine at this time (based on all information available, including the data obtained in 5.5) whether the well is characterized by a low, intermediate, or high yield. If the PI feels that enough information is available to define the well type, testing shall proceed with item 5.8. If the PI determines that additional testing is needed, it shall proceed so as to minimize disturbance to the aquifer(s) under test.

5.6.1 Conduct a slug test.

5.6.1.1 Rapidly extract 1-2 ft of fluid from the well.

5.6.1.2 Monitor and record the fluid level as it recovers.

5.6.1.3 If the fluid recovers more slowly than 1 foot/minute the well is of a low yield type. Skip the remainder of 5.6.1 and initiate 5.7.

5.6.2 Conduct a second slug test at a higher drawdown.

5.6.3 If necessary , conduct a controlled, short term well production test (pump test) to further characterize the overall hydraulics of the wellbore.

5.6.3.1 Select the pumping rate as follows: The rate(s) of pumping are determined by drawdown information previously obtained or at rate(s) appropriate for the wellbore diameter and saturated interval thickness. The appropriate extraction rate is a function of length of saturated interval, borehole diameter, and previous well

© 2008, RAS, Inc.

yield knowledge. The appropriate pumping procedures to be employed are also dictated by the length of the exposed rock interval. In general, the extraction flow rate should be sufficient to induce adequate inflow from the producing intervals. The concern is that the extraction flow rate does not cause extreme drawdown within the well i.e. lowering the free water surface to the depth of the shallowest conductive interval.

5.6.3.2 Treat extracted water as follows: On-site pre-treatment of groundwater using activated carbon, can be conducted prior to DI water generation, if there is a contaminated groundwater source. In addition, on-site treatment can also be considered to handle extracted fluids that would require containerization and treatment prior to disposal.

5.6.3.3 While extraction proceeds, manually record elapsed time of pumping, depth to water determined using a hand-held water level indicator, total gallons extracted, and extraction flow rate. This provides a manual back-up of the data recorded digitally during the test.

5.6.3.4 Continue pumping until at least three wellbore volumes have been extracted from the wellbore, or a stabilized water level elevation is obtained. Record wellbore volume.

5.7 Review data obtained during the pumping test to determine pumping and logging procedures.

Extraction procedures for detection and characterization of hydraulically conductive intervals are determined based on the pumping test information. The emplacement, testing and pumping procedures will differ depending upon well yield and determined lengths of intervals of interest. In wellbore situations where intervals of interest are small (less than 30 feet) and hydraulic characteristics observed during drilling and preliminary hydraulic testing indicate hydraulically conductive intervals with extremely low flow rates (i.e. <0.10 gpm/foot of drawdown), a slug testing procedure may be employed. In wellbore cases where the preliminary hydraulic testing indicates low to moderate total yield (i.e. $0.10 < Q < 4$ gpm/foot of drawdown), constant low flow rate pumping after DI water emplacement procedures may be employed. In wellbore situations where intervals of interest are large, and high total yield (i.e. > 4 gpm/foot of drawdown) is observed, constant pumping during DI water injection procedures shall be employed.

© 2008, RAS, Inc.

5.8 DI water emplacement

After the PI has determined the test protocol, the fluid in the well shall be replaced again with DI water, following the procedure outlined in 5.5.1 above.

5.9 Conduct active flow testing

5.9.1 Low yield active test procedure:

If the well is of low yield type, proceed as follows:

5.9.1.1 Perform a slug test in accordance with procedures developed by Hvorslev (1951). Rapidly extract a small volume of water from near the free water surface using the extraction riser and pump. A drop in piezometric head of 2-10 feet should be adequate for the initial test. Record the rise in the free water surface with time using the pressure transducer, and develop a conventional time-lag plot. Log the well continuously with the HpL sonde to monitor changes in the fluid column.

5.9.1.2 The completion of the slug test shall be defined as follows: Either (a) 80% of the head disturbance has decayed, or (b) a 20-hour time period has elapsed, whichever occurs first.

5.9.1.3 Repeat the DI emplacement procedure 5.8 and the low yield active test procedure 5.9.1 with successive increases in the drop of piezometric head (or volume extracted) associated with each slug test. Let the wellbore recover and record the rise in the free water surface. Repeat logging of the wellbore fluid after the free water surface has recovered to a satisfactory elevation.

5.9.1.4 The number of repetitions shall be determined by the PI in the field after review of previous results.

5.9.1.5 Record digitally the data from the pressure transducer throughout the test. Periodically manually record the borehole fluid level.

5.9.2 Moderate yield active test procedure:

Time Series Hydrophysical Logging During Continuous Pumping After DI water Emplacement

© 2008, RAS, Inc.

5.9.2.1 The PI shall select a pumping rate such that drawdown of the free water surface produced during pumping shall not overlap any identified water producing interval.

5.9.2.2 Maintain a constant flow rate from the evacuation pump and record the total volume of groundwater evacuated from the wellbore. Employ a continuous reading pressure transducer (or equivalent device) to monitor and record digitally the depressed total head during pumping, along with the associated pumping rate. Manually record depth to water and the flow data.

5.9.2.3 Conduct HydroPhysical logging continuously. The number of logging runs and the length of time required to conduct all logging is a function of the particular hydraulic conditions.

5.9.2.4 Logging and pumping shall continue until the FEC of the fluid in the affected interval is more than 80% the FEC of the formation water.

5.9.2.5 This process may be repeated, at the PI's discretion, starting with DI emplacement procedure 5.6 and the moderate yield active test procedure 5.7.2, increasing the pumping rate.

5.9.2.6 The number of repetitions is determined in the field after review of previous results.

5.9.2.7 Record digitally the data from the pressure transducer and from the extraction line flow meter throughout the test.

5.9.3 High yield active test procedure.

Time Series Wellbore Fluid Logging During Continuous Pumping and Simultaneous DI Water Injection

5.9.3.1 The RAS PI shall select a pumping rate such that drawdown of the free water surface produced during pumping does not overlap any identified water producing interval.

5.9.3.2 Maintain a constant flow rate from the evacuation pump and record this rate and the associated drawdown. During this period, conduct HydroPhysical logging until reasonably similar Hydrophysicallogs are observed and a reasonably stable drawdown is achieved.

© 2008, RAS, Inc.

5.9.3.3 After reasonably similar downhole fluid conditions are observed and simultaneous with extraction pumping, inject DI water at the bottom of the well at a constant rate of 10 to 30% of that employed for extraction. Increase the total rate of extraction to maintain total formation production reasonably similar to that prior to DI water injection (i.e. increase the total extraction by amount equal to the DI water injection rate).

5.9.3.4 Continuous logging shall be conducted until stabilized and consistent diluted FEC logs are observed. A minimum of 6 downward logs shall be recorded in the stable, diluted condition prior to terminating the test.

5.9.3.5 After stabilized and consistent FEC logs are observed, terminate DI water injection. Reduce the total extraction flow rate to the net formation rate and conduct continuous logging. Conduct logging until stable and consistent FEC values are observed.

5.9.3.6 Record digitally the data from the pressure transducer and from the extraction and injection line flow meters throughout the test.

5.9.3 If inflow characterization at a second pumping rate is desired, the following procedure shall be followed:

5.9.3.1 Terminate DI injection.

5.9.3.2 Increase the extraction rate to the new value.

5.9.3.3 Follow the procedures detailed in 5.9.3.1 to 5.9.3.6.

5.9.4 Although pumping and testing procedures vary depending upon wellbore hydraulics and construction detail, there are several requirements which are common to all of the active tests described above.

5.9.4.1 Periodically record the total volume and flow rate of well fluids extracted and the total volume and flow rate of DI water injected. Use a continuous reading pressure transducer or similar device to monitor the depressed total head during pumping. Manually record the depressed total head (piezometric surface) periodically, with the associated pumping and injection data.

© 2008, RAS, Inc.

5.10 Depth Specific Sampling

At the conclusion of hydrophysical testing, downhole, depth specific sampling can be conducted. The contamination concentration values derived from the collected samples, in conjunction with the hydrophysical logging results, can be used to estimate the interval specific contaminant concentration for the sampled hydraulically conductive intervals.

5.10.1 Pumping at the same formation production rate as employed during hydrophysical testing is initiated, or maintained.

5.10.2 Periodic FEC/Temperature logs are conducted during pumping until stable logs are observed and any residual DI water has been pumped out of the well.

5.10.3 Based on review of the hydrophysical logging results, the location of the water bearing intervals are identified and sampling depths are selected. Typically, the sampling depth is located 1-5 feet above an identified water bearing interval.

5.10.4 Prior to each sampling run, the inside of the sampler barrel and petcock are thoroughly cleaned with deionized water and Alconox soap, rinsed with DI water and dried off.

5.10.5 The sampler ports are closed at the surface. The operator will physically confirm that the ports are closed prior to placing in the wellbore.

5.10.6 Depth datum for the location of inlet port is referenced to same datum as hydrophysical logging.

5.10.7 The sampler is lowered to the selected depth, opened for at least 5 minutes to insure complete filling, closed and withdrawn to the surface. At the surface, the ASDE is recorded and the sampler is decanted into laboratory containers and reassembled.

5.10.8 Prior to each sampling run, the inside of the sampler barrel and petcock are thoroughly cleaned with deionized water and Alconox soap, rinsed with DI water and dried off.

5.10.9 Procedures 5.10.6 through 5.10.8 repeated until all selected intervals sampled.

© 2008, RAS, Inc.

5.11 Post-log calibration

Carry out post-log calibration, following procedures in TP-FEC.

5.12 Departure from site

5.12.1 Turn all pumps off. Clean evacuation line and outside of pump as required by site-specific procedures.

5.12.2 Remove the tool from the well. Clean the wireline and the tool as required by site-specific procedures.

5.12.3 Remove the injection line from the well. Clean the injection line as required by site-specific procedures.

5.12.4 Store the pumps and logging tools properly for transport.

5.12.5 Place cover on well and lock (if available).

6.0 RECORDS

Records of the data obtained from each measurement shall be produced as follows:

6.1 Paper copies of HpL logs shall be provided as shown in Appendix 7.9.

6.2 Digitally acquired flow, pressure, and head data shall be recorded along with on-site calibration data.

6.3 Forms shall be completed as detailed in this procedure and in TP-13.

6.3.1 As provided by contractor.

6.4 Exceptions shall be handled as detailed in TP-13.

6.5 Field Modifications shall be handled as detailed in TP-13.

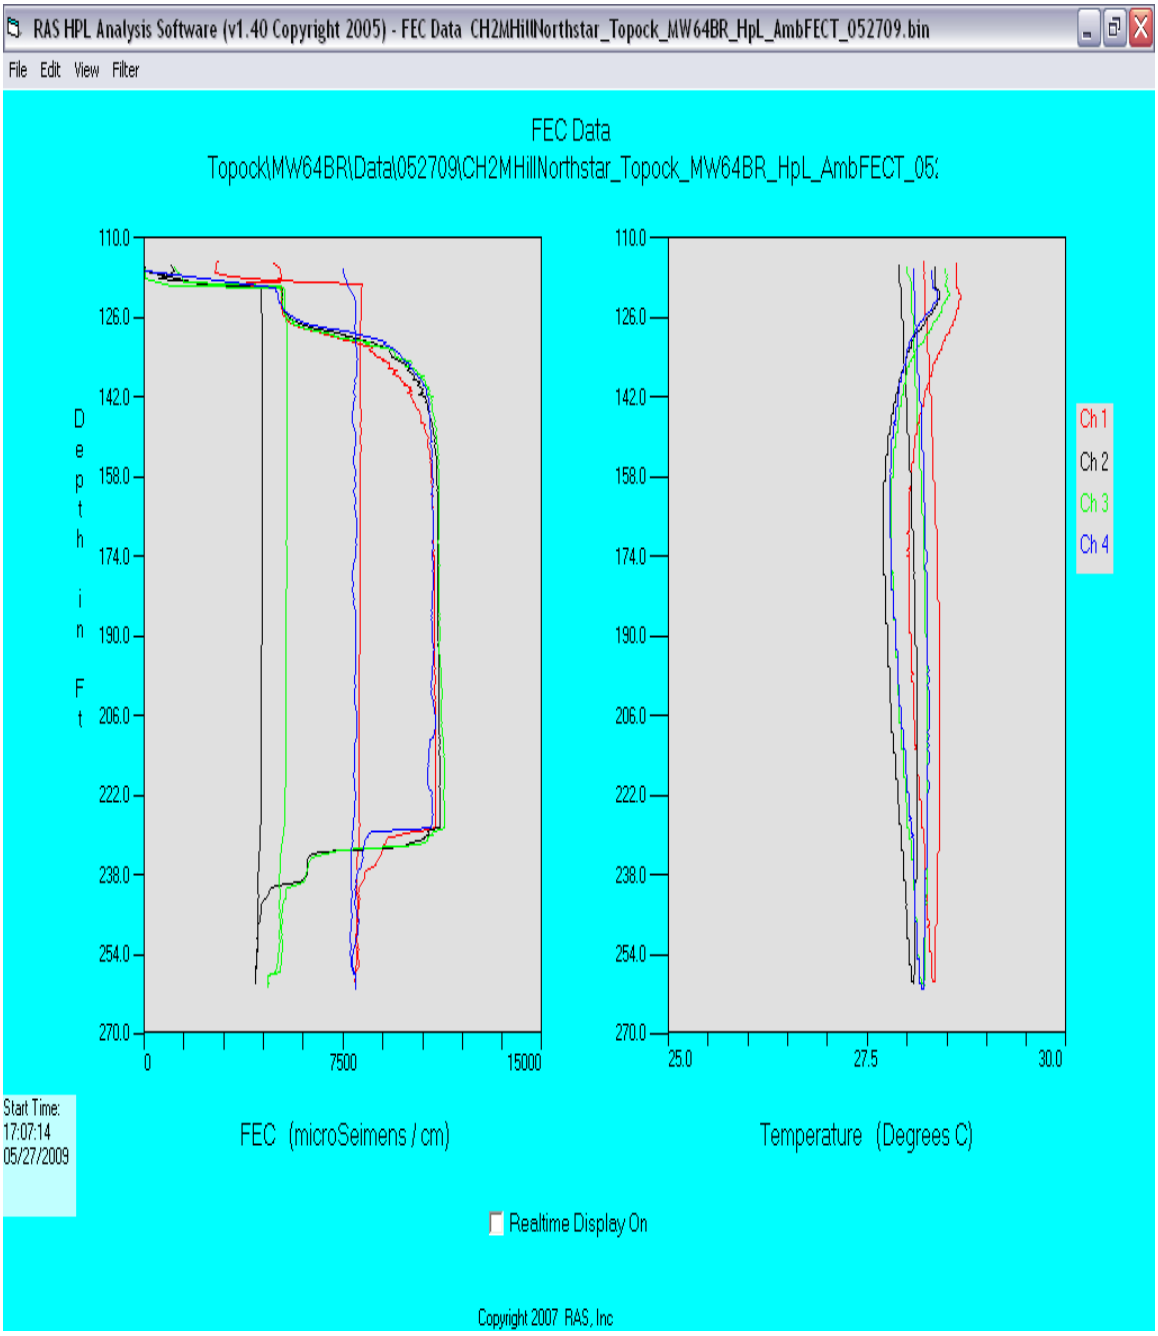

Figure 1. MW-64BR Ambient FEC and Temperature Log, **Note:** Bentonite plug @ 230' fouling all 4 sensors. Well screen was pressure washed with DI water and bentonite material removed from well.

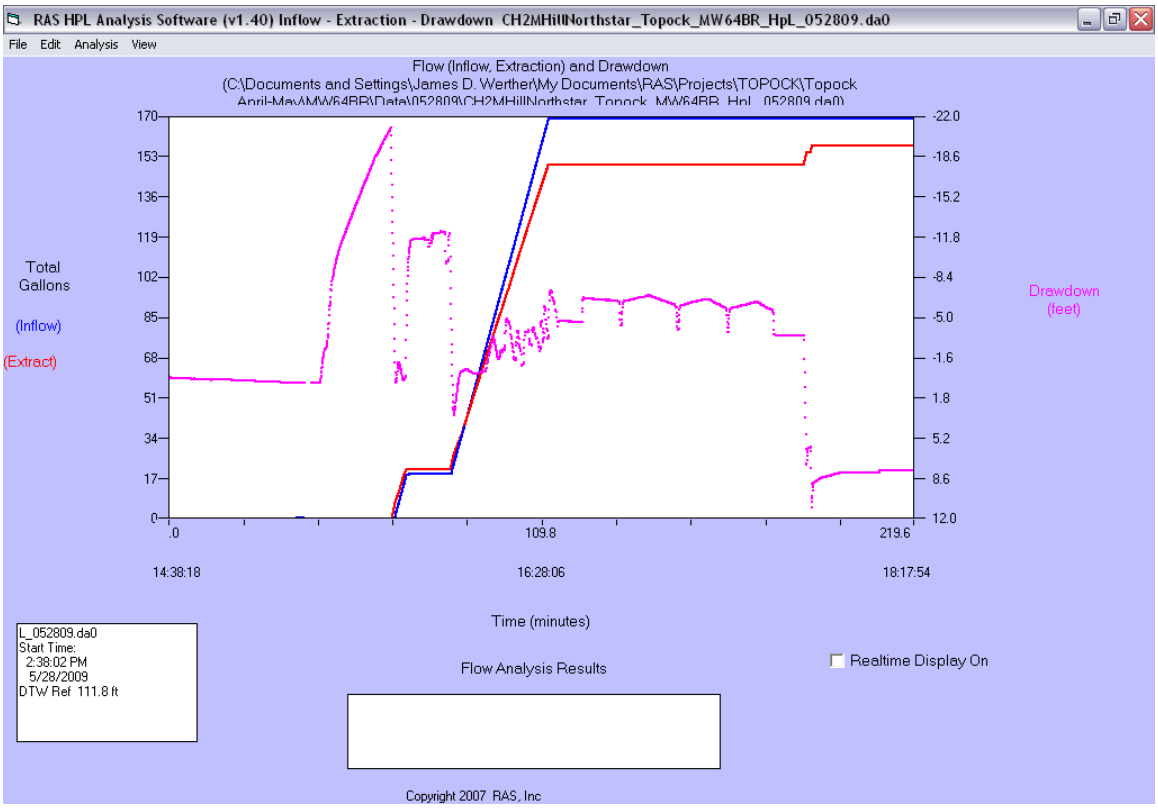

Figure 2. MW-64BR Pressure data – during pressure washing and pumping of well to clean out screen of bentonite material.

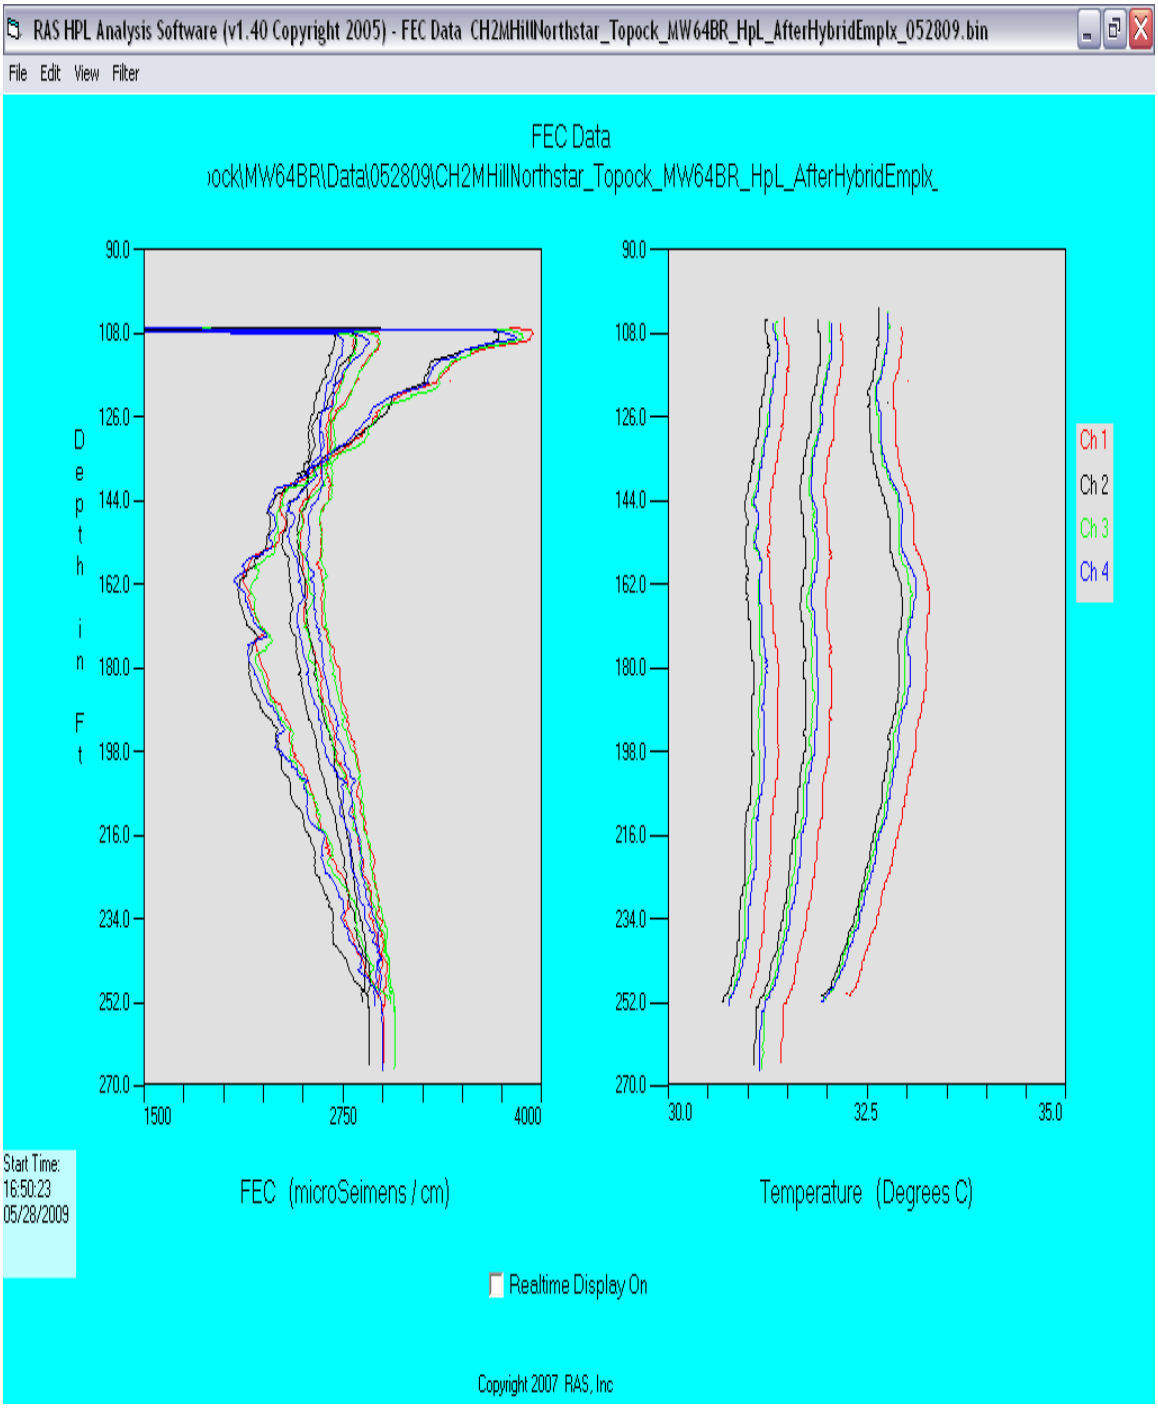

Figure 3. MW-64BR Post pressure washing of screen logs. Material previously fouling HPL tool sensors removed. Tool performed properly as demonstrated by these logs.

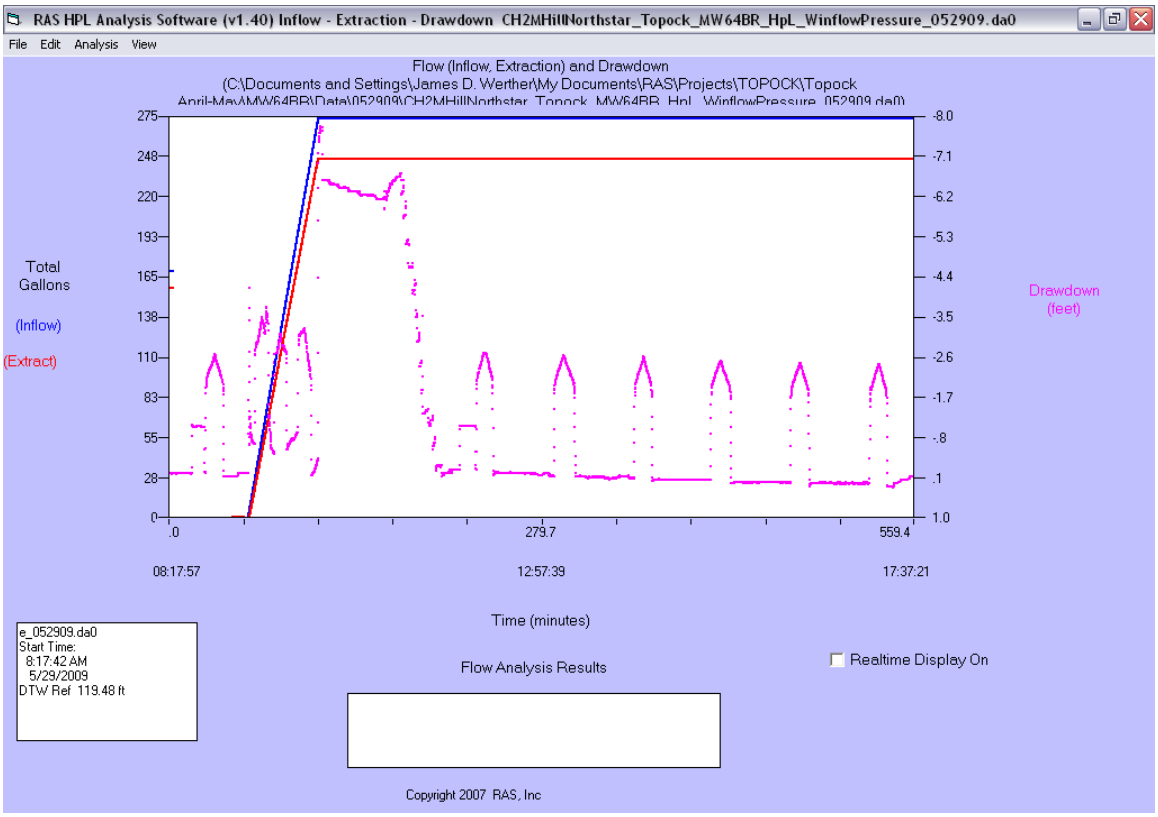

Figure 4. MW-64BR Flow and Pressure Data During Emplacement and Ambient Flow Characterization. Day 1 data.

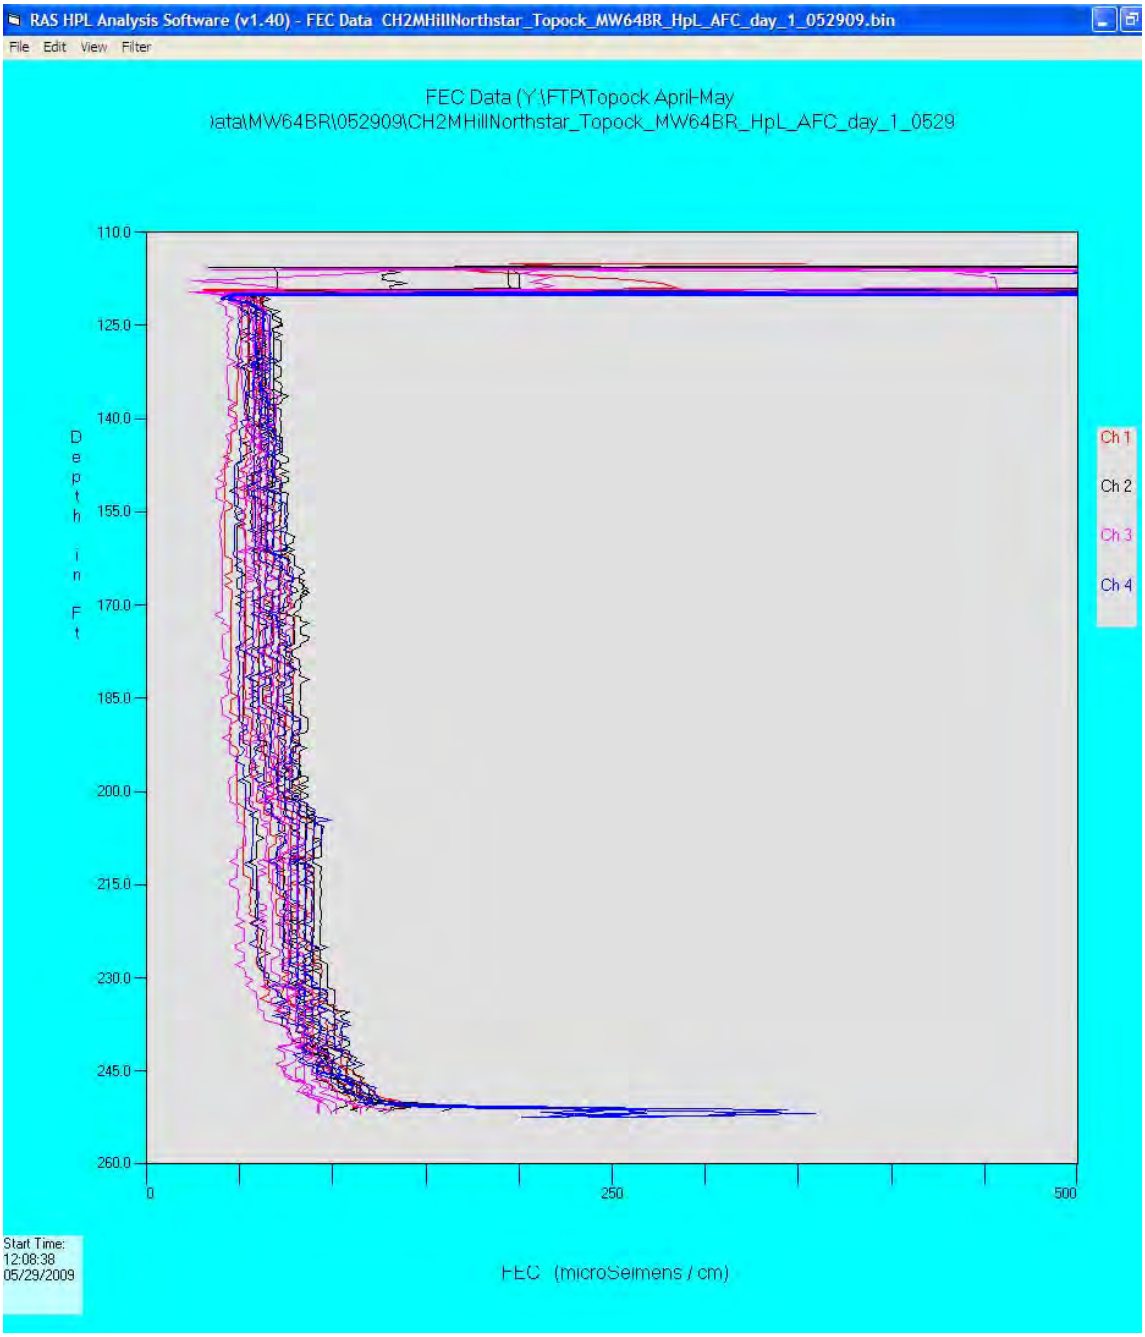

Figure 5. MW-64BR, Summary of Logs collected during Day 1 of Ambient Flow Characterization.

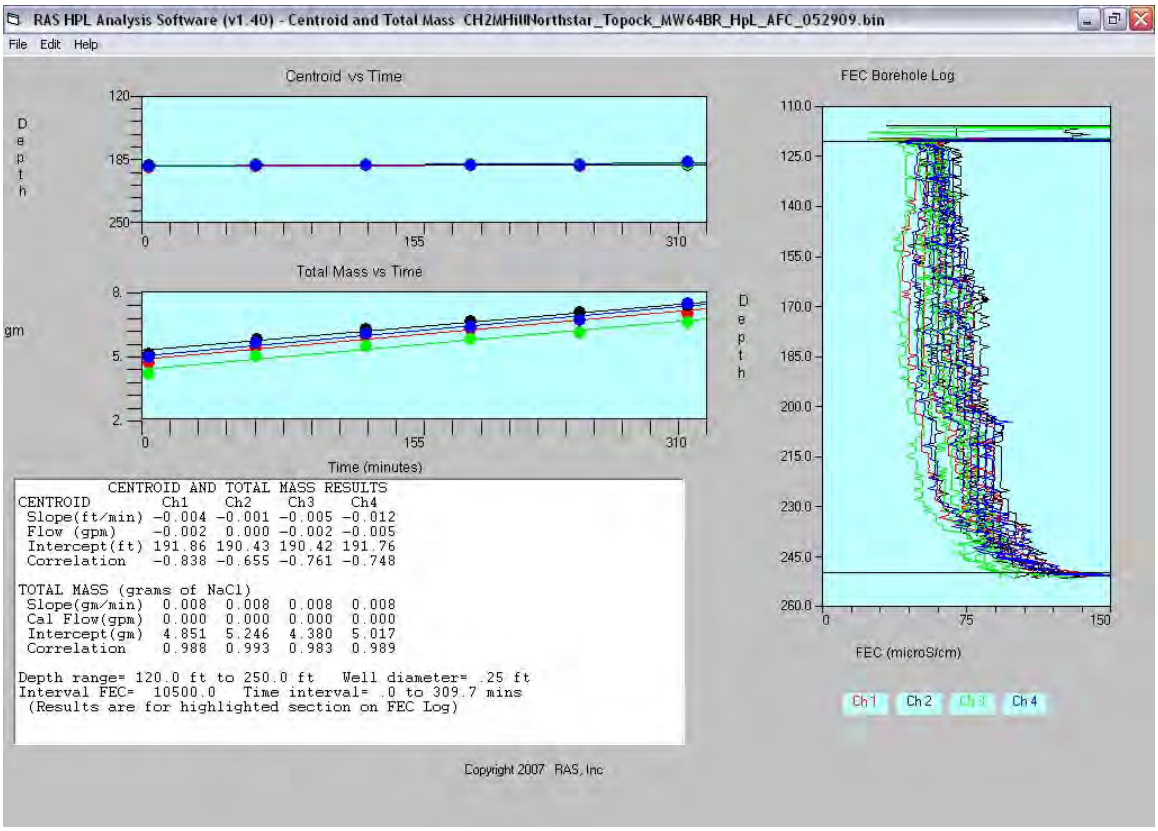

Figure 6. MW-64BR Centroid & Total Mass Analysis – AFC Day 1- Data suggest flow was less than 0.001 gpm.

053009 – Ambient Flow Characterization Day 2

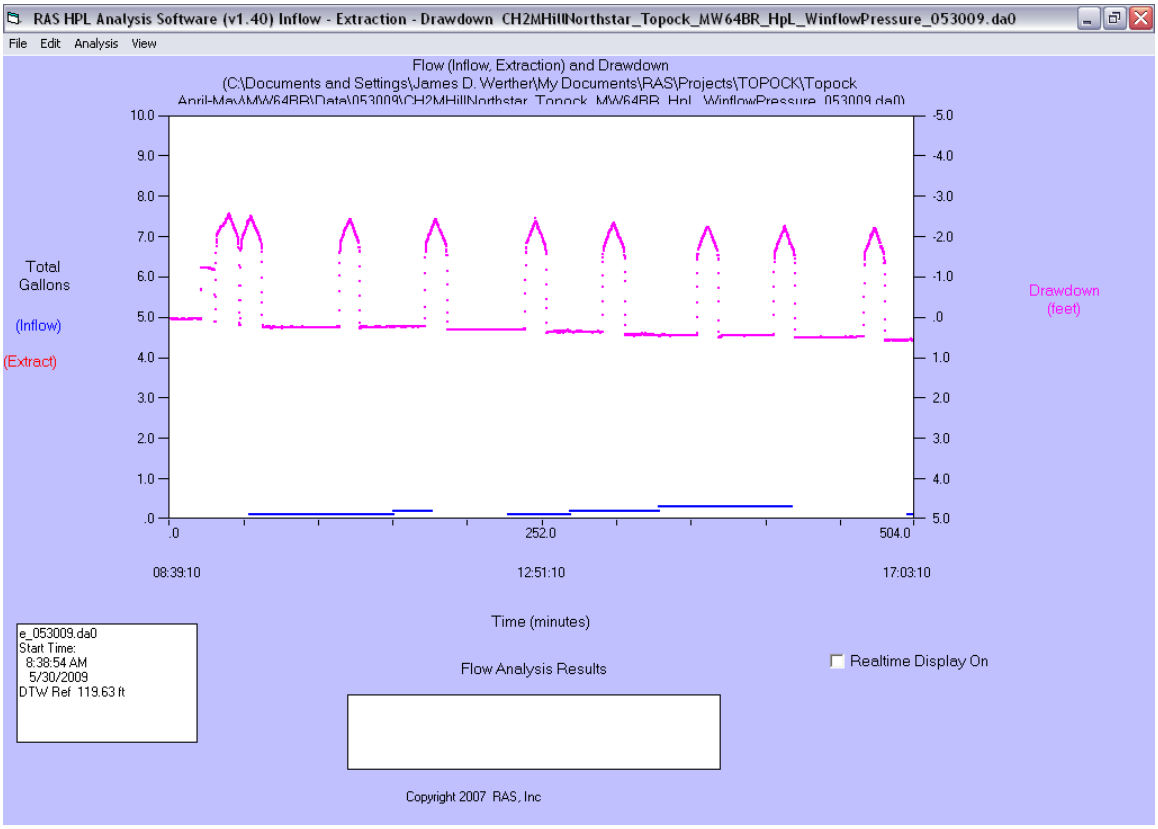

Figure 7. MW-64BR Pressure history during Day 2 of Ambient Flow Characterization.

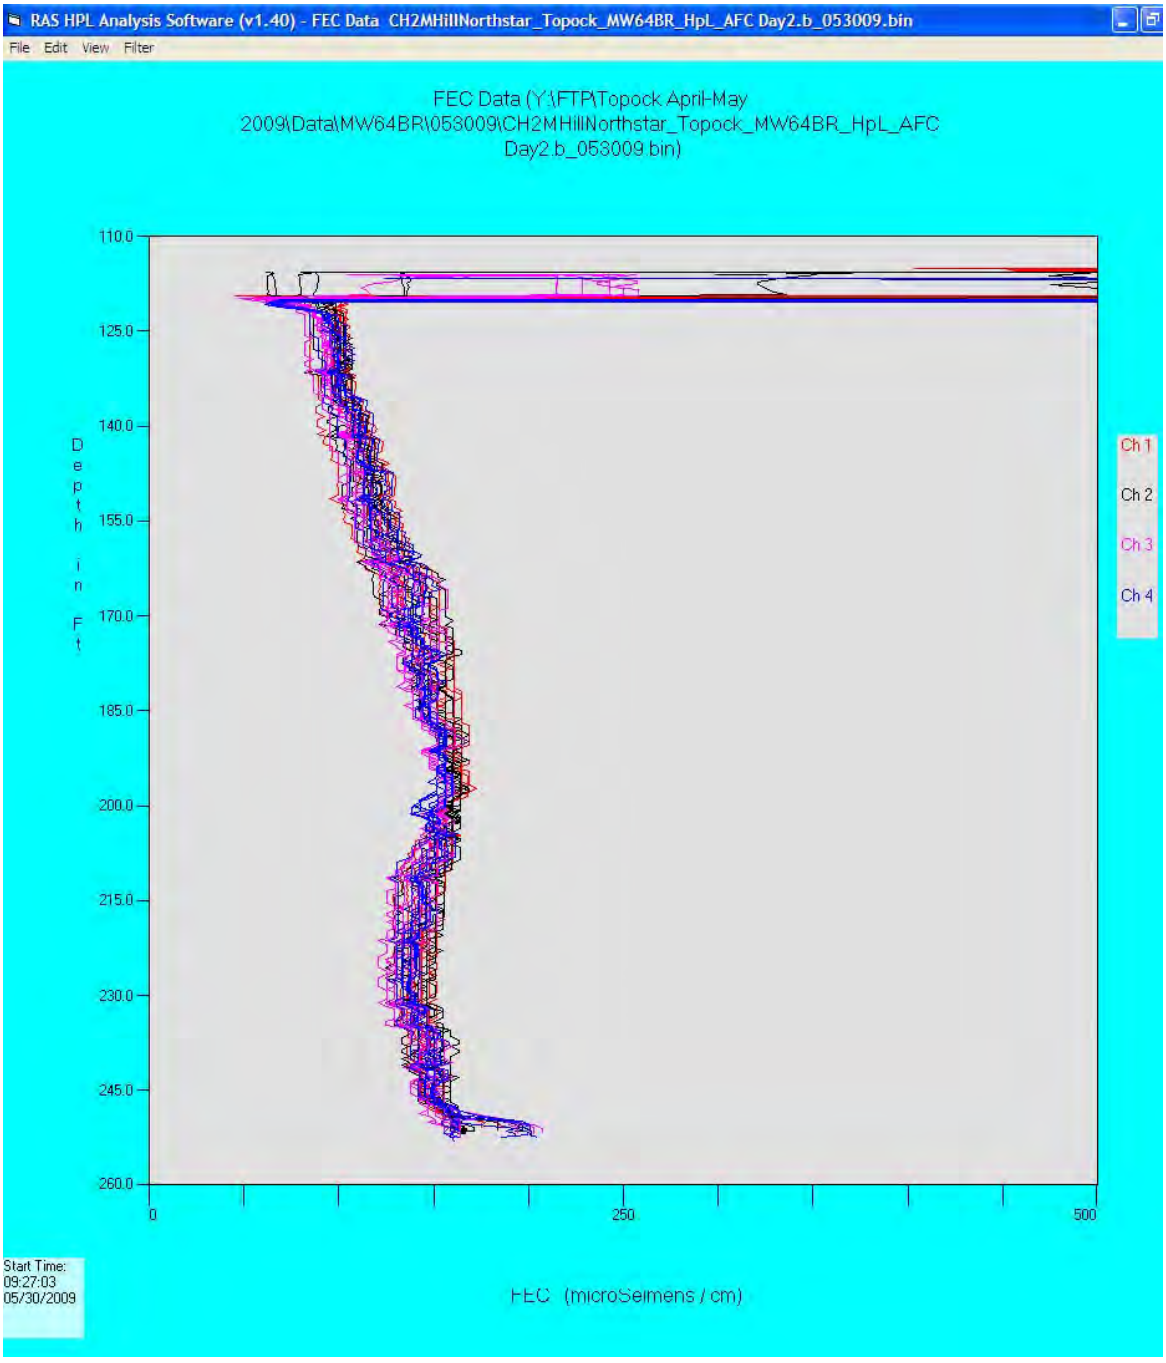

Figure 8. MW-64BR, Summary of Logs collected during Day 2 of AFC.

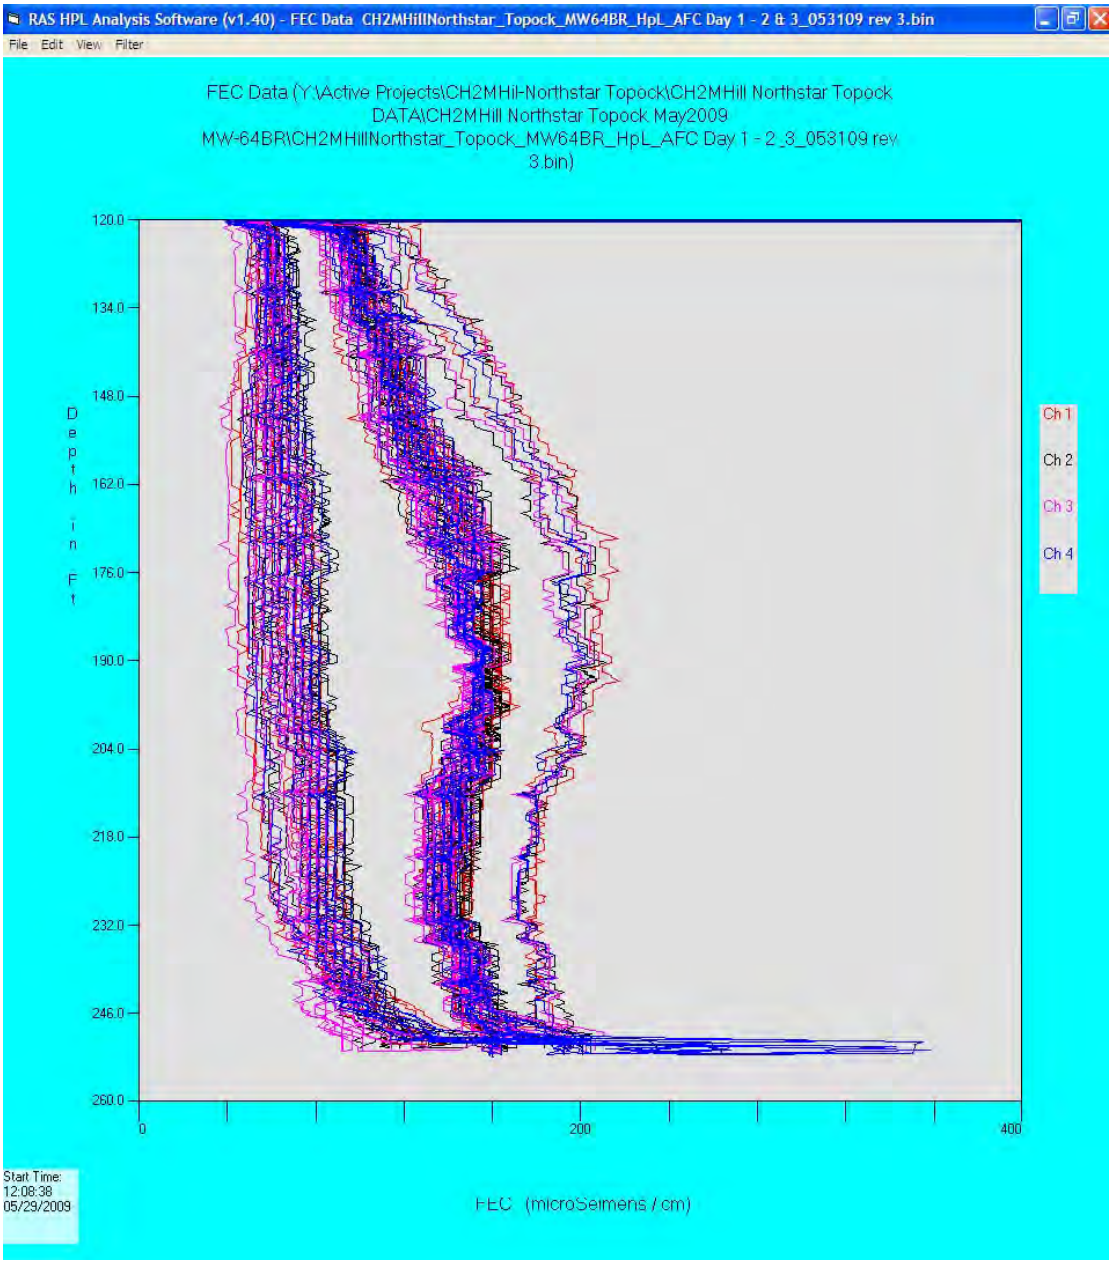

Figure 9. MW-64BR, AFC Days 1, 2 and 3 compiled for analysis.

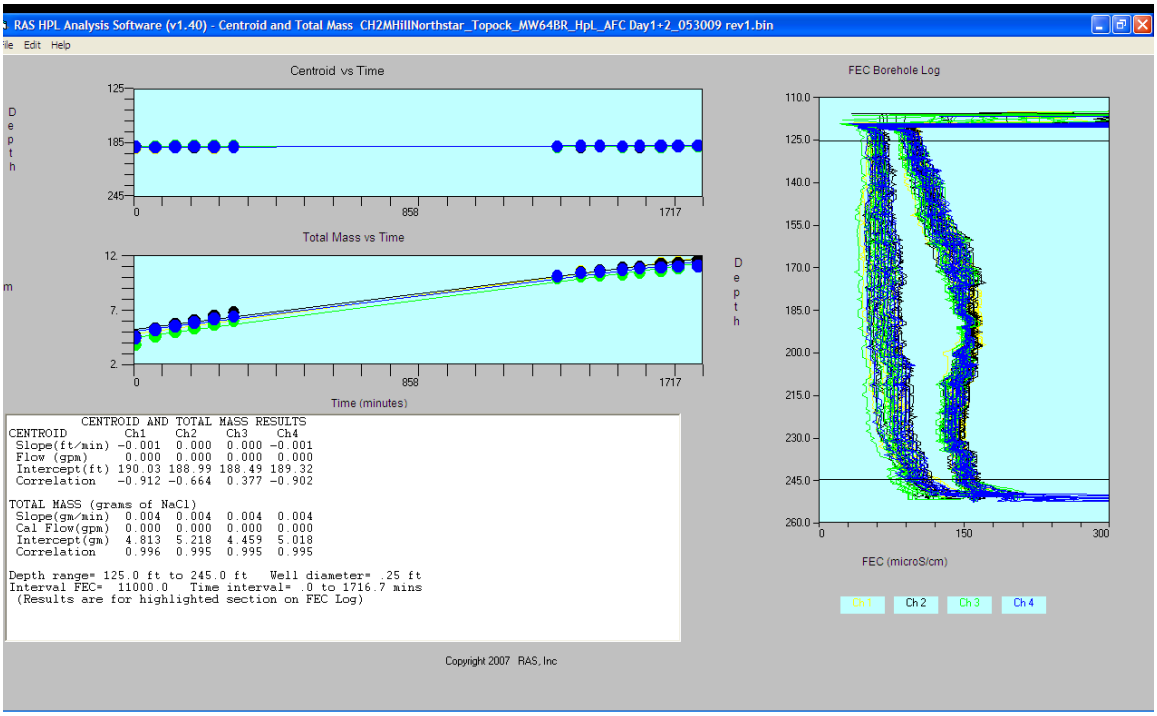

Figure 10. MW-64BR Integral and Centroid Analysis of HPL Data Collected on Day 1 and Day 2. Still below 0.001 gpm

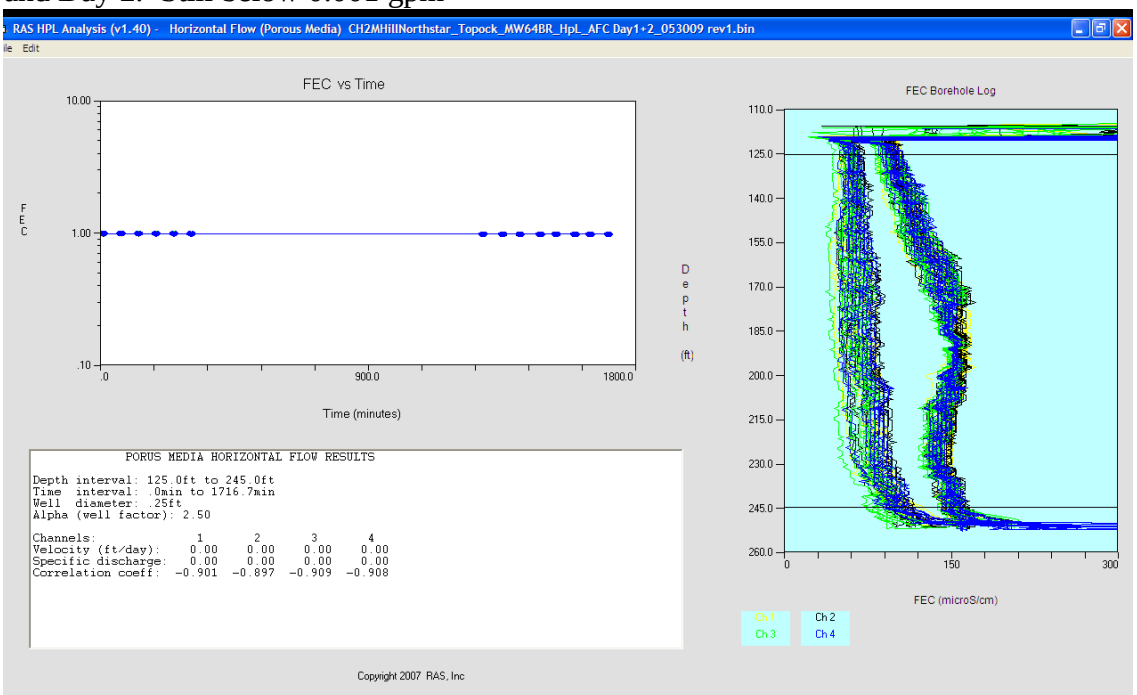

Figure 11. MW-64BR, Traditional Dilution Analysis of HPL Data Collected on Day 1 and Day 2. Flow velocity less than 0.01 feet per day.

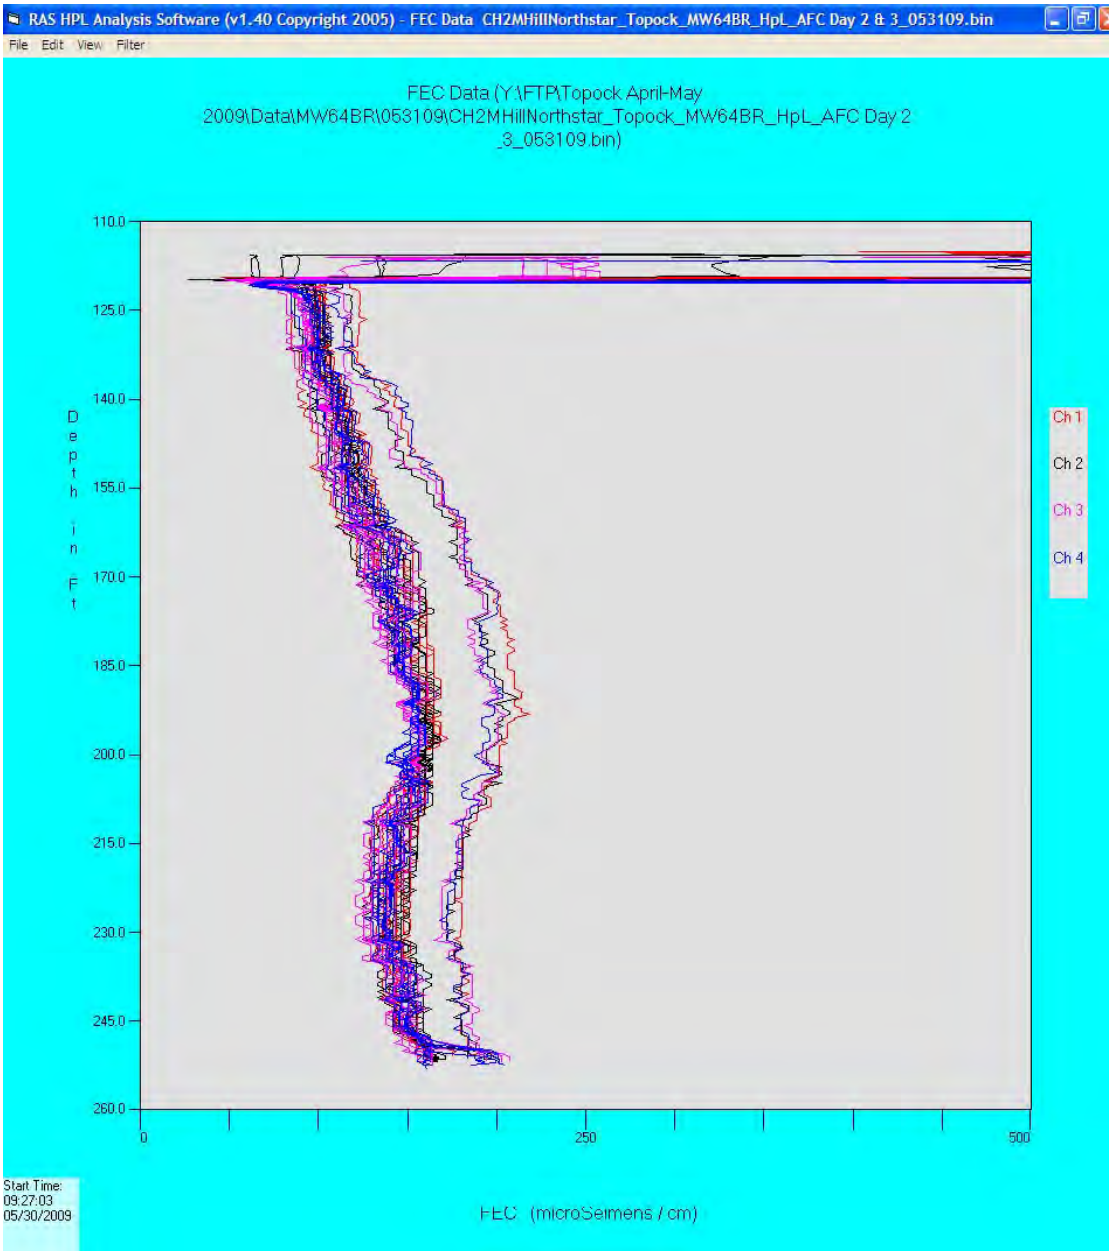

Figure 12. MW-64BR, Summary of Logs from Day 2 and single log collected in AM of Day 3.

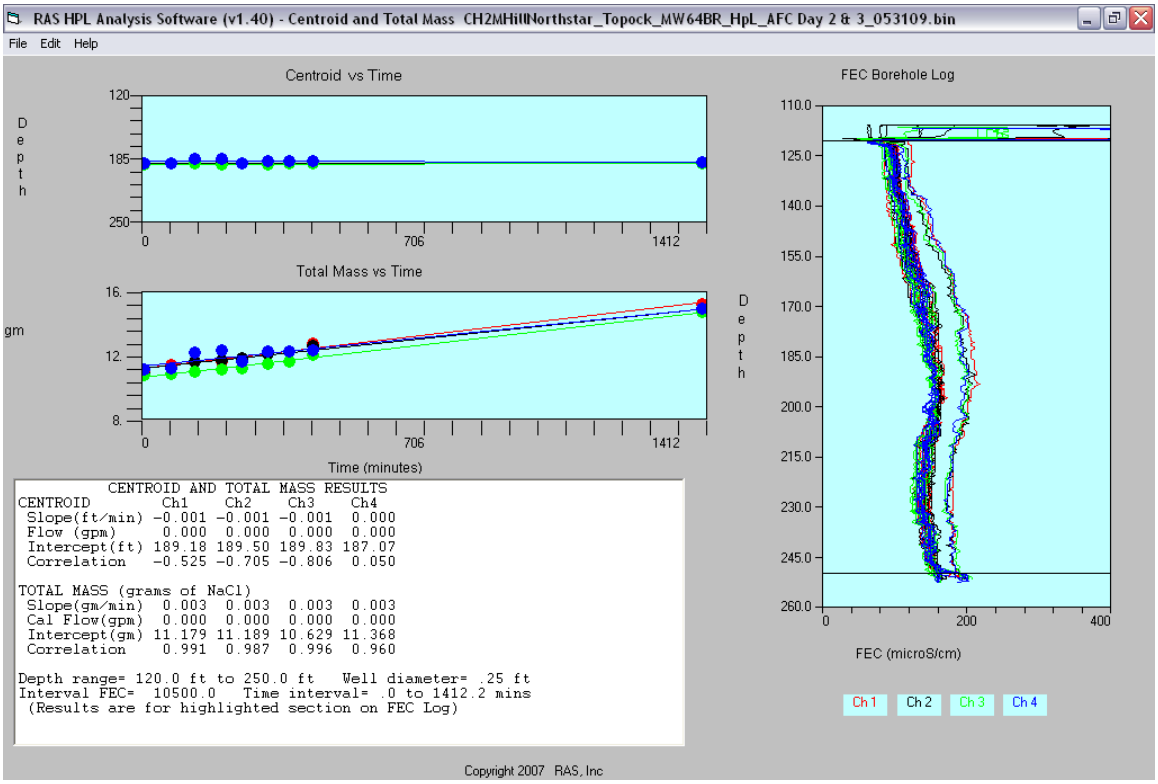

Figure 13. MW-64BR Centroid & Total Mass Analysis - AFC Day 2 & 3 - Data suggest flow was less than 0.001 gpm.

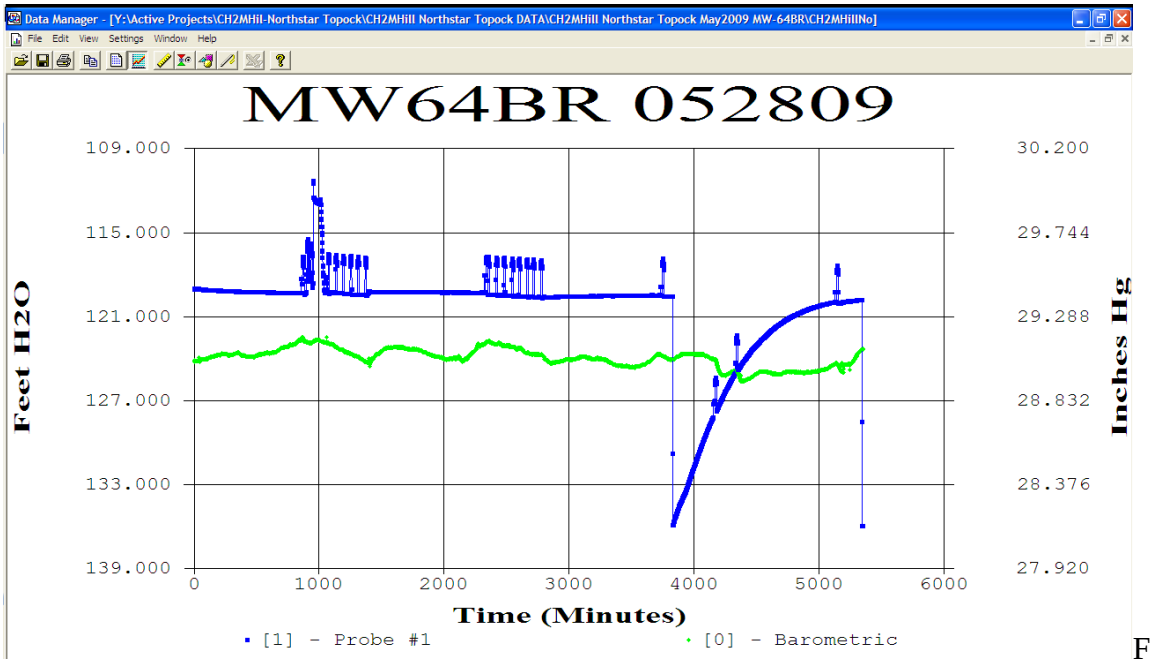

Figure 14. MW-64BR Complete Pressure History During HPL Testing, T = 0 @ 5/28/09 20:18 hours. Pressure monitoring completed at 6/1/09 13:34 hours. AFC logging noted by series of pressure spikes. Slug test and recover at ~ 3800 minutes.

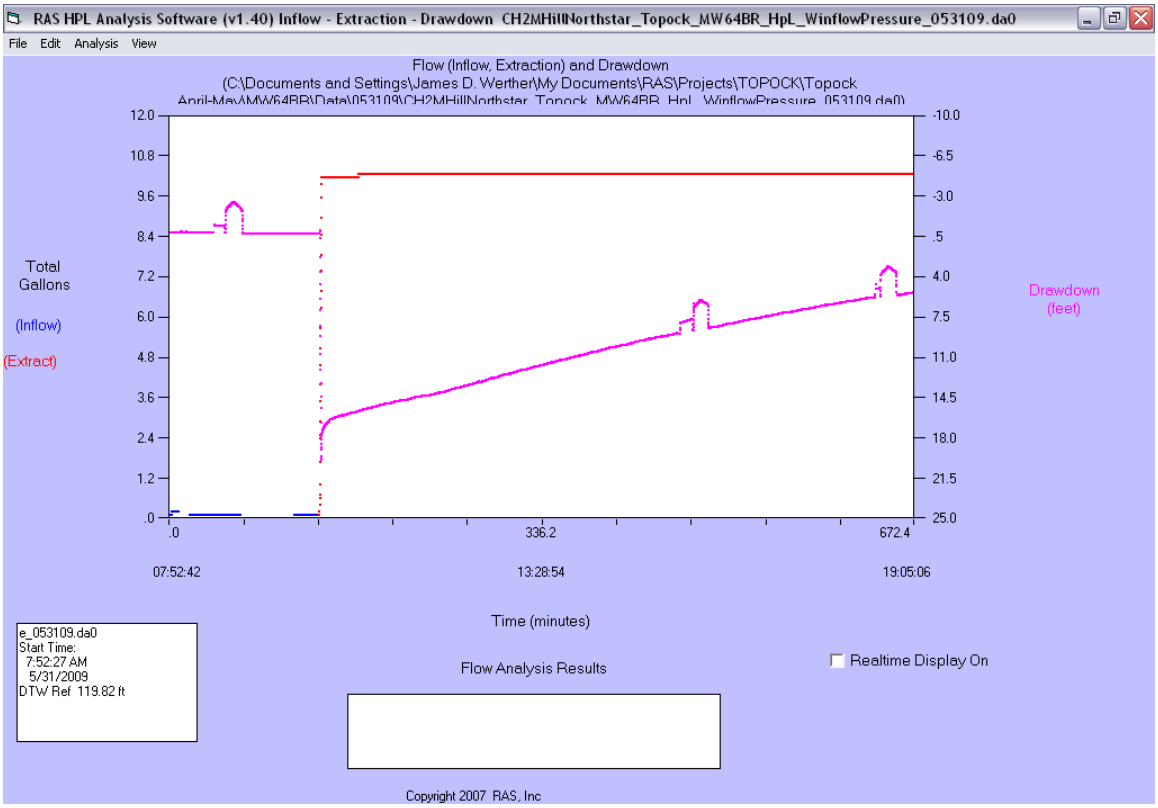

Figure 15. MW-64BR. Pressure history during Slug Test After Emplacement Procedures (SAE)

Volumetric Average Flowrate Calculations (average inflow rate from rising head data and casing diameter)

T1 = 153 min @ 16.1 feet

T2 = 639 min @ 5.6 feet

dT = 486 minutes
dDD = 10.5 feet

In 3 inch well, 1 foot = 0.367 gallons

Therefore,
(10.5*0.367)/486 mins = 0.008 gpm

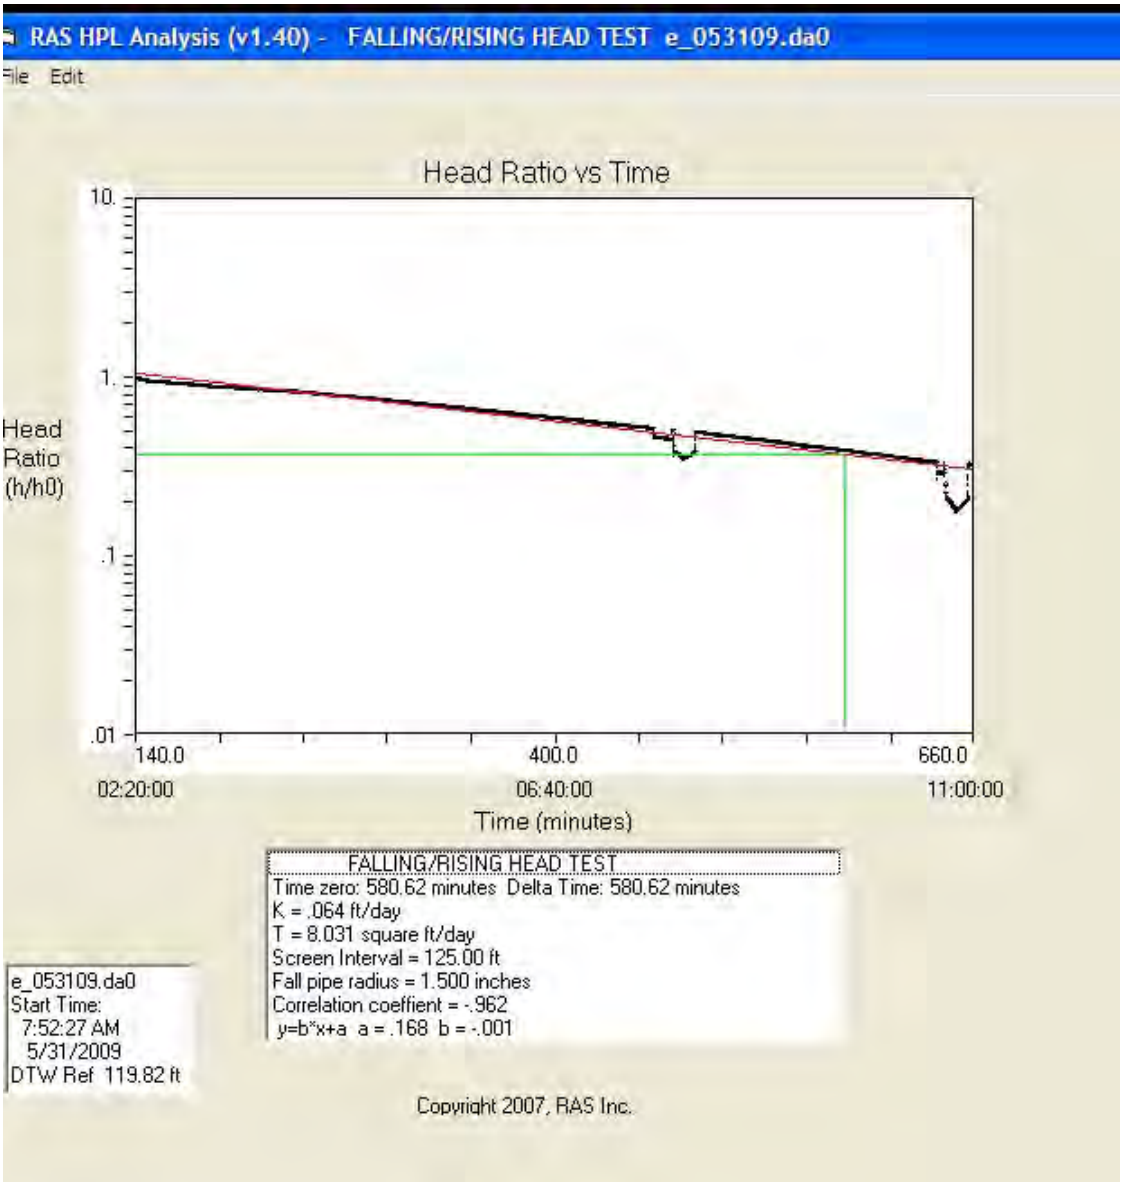

Figure 16. MW-64BR. Rising Head Test Analysis

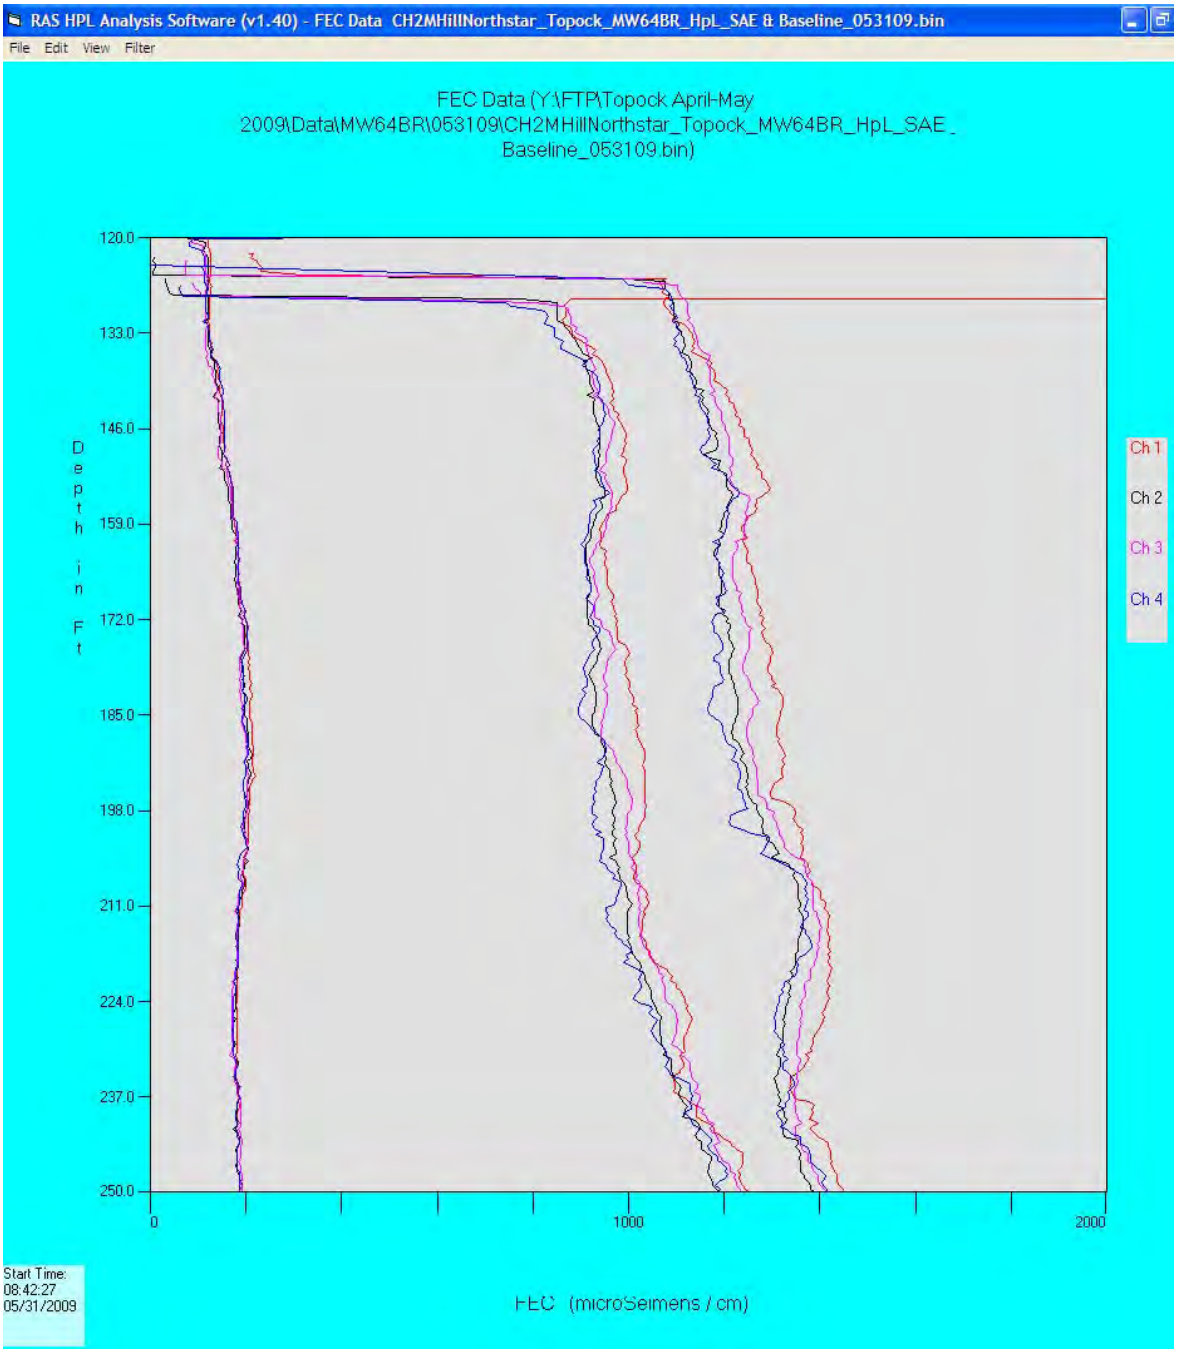

Figure 17. MW-64BR. Summary of Logs collected during SAE test. 16 foot slug removed.

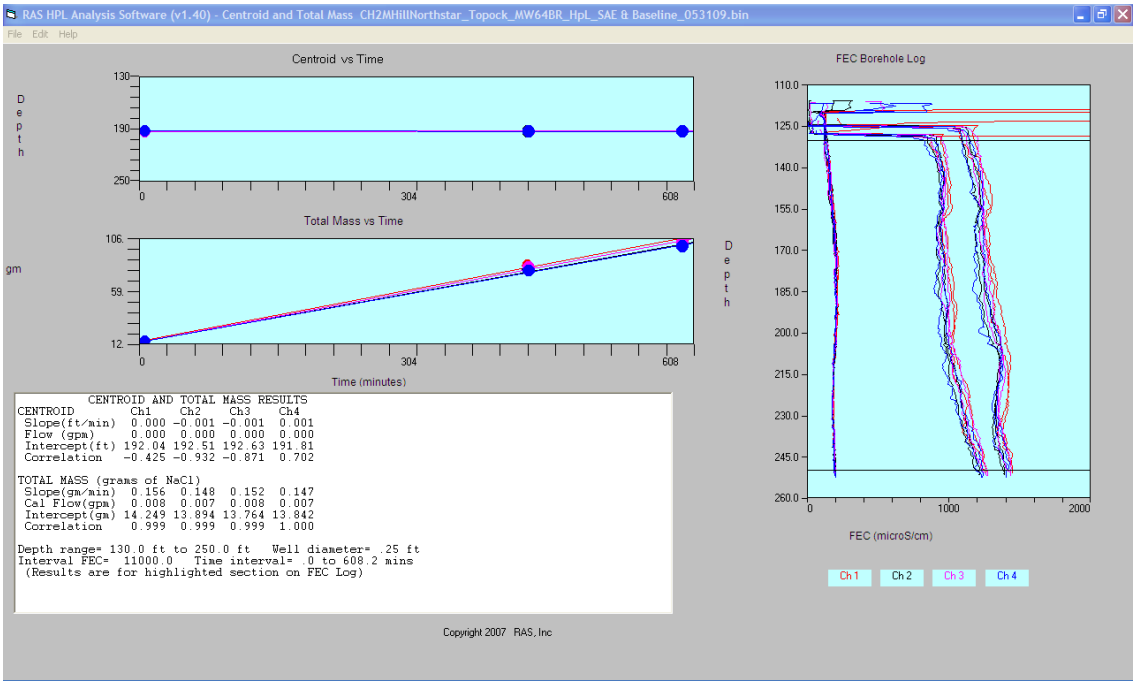

Figure 18. MW-64BR Centroid Total Mass Analysis – Total Formation Production 0.008 gpm and compares very favorably with average formation flow calculated volumetrically from rising head data (above).

SAE FEC (µS/cm): 0 400 800 1200 1600
Estimated Hydraulic Conductivity (ft/day): E-2 E-1 E+0

PVC Conductor Casing
1" Grouted Borehole
Fabric Liner Directly Against Open Borehole
14" Borehole with Fabric Liner
Water Level 577 (approx.)
Fabric Liner Held Slightly away from Borehole Wall
Monitoring Zone 1
3/8" Tube Welded to Fabric Liner, Extends to Surface
Monitoring Zone 2
Monitoring Zone 3
<0.001 gpm
0.008 gpm
6.4 E-2 ft/day
Total Depth 257'

TABLE C1-1

Soil Sample Results: Metals

Inside the Compressor Station

Revised Addendum to the Summary or Findings Associated with the East Ravine Groundwater Investigation

PG&E Topock Compressor Station, Needles, California

Notes:

1 Commercial screening level - commercial DTSC CHHSL. If the commercial DTSC CHHSL is not established, the USEPA regional screening level is used.

2 CH2M HILL. 2009. "Final Soil Background Technical Memorandum at Pacific Gas and Electric Company Topock Compressor Station, Needles, California." May.

3 Commercial screening level is below background values therefore arsenic results are only screened against background.

Results greater than or equal to the Background levels are bolded

NE = not established

USEPA = United States Environmental Protection Agency

DTSC = California Department of Toxic Substances Control

CHHSL = California human health screening levels

-- = not analyzed

FD = Field Duplicate

ft bgs = feet below ground surface

J = concentration or reporting limit estimated by laboratory or data validation

mg/kg = milligrams per kilogram

N = Primary Sample

ND = not detected at the listed reporting limit

TABLE C1-4

Soil Sample Results: Contract Laboratory Program Inorganics

Outside the Compressor Station

Revised Addendum to the Summary or Findings Associated with the East Ravine Groundwater Investigation

PG&E Topock Compressor Station, Needles, California

Notes:

1 Residential screening level - residential DTSC CHHSL. If the residential DTSC CHHSL is not established, the USEPA regional screening level is used.

2 ARCADIS. 2008. "Technical Memorandum 3: Ecological Comparison Values for Metals and Polycyclic Aromatic Hydrocarbons in Soil."

May 28. ARCADIS. 2009. "Topock Compression Station - Final Technical Memorandum 4: Ecological Comparison Values for Additional Detected Chemicals in Soil." July 1.

3 CH2M HILL. 2009. "Final Soil Background Technical Memorandum at Pacific Gas and Electric Company Topock Compressor Station, Needles, California." May.

Results greater than or equal to the interim screening level are circled.

NE = not established

USEPA = United States Environmental Protection Agency

DTSC = California Department of Toxic Substances Control

CHHSL = California human health screening levels

-- = not analyzed

FD = Field Duplicate

ft bgs = feet below ground surface

J = concentration or reporting limit estimated by laboratory or data validation

mg/kg = milligrams per kilogram

N = Primary Sample

ND = not detected at the listed reporting limit

Notes:

1 Commercial screening level - commercial DTSC CHHSL. If the commercial DTSC CHHSL is not established, the USEPA regional screening level is used.

2 CH2M HILL. 2009. "Final Soil Background Technical Memorandum at Pacific Gas and Electric Company Topock Compressor Station, Needles, California." May.

NE = not established

USEPA = United States Environmental Protection Agency

DTSC = California Department of Toxic Substances Control

CHHSL = California human health screening levels

Calculations:

BaP equivalent = Sum of Result x TEF, 1/2 reporting limit used for nondetects. If all PAHs are nondetect, the final qualifier code is U.

PAHLow = Sum of Result of low molecular weight PAHs, zero is used for nondetect values.

PAHHigh= Sum of Result of high molecular weight PAHs, zero is used for nondetect values.

-- = not analyzed

µg/kg = micrograms per kilogram

FD = Field Duplicate

ft bgs = feet below ground surface

J = concentration or reporting limit estimated by laboratory or data validation

N = Primary Sample

ND = not detected at the listed reporting limit

TABLE C1-6

Soil Sample Results: Polycyclic Aromatic Hydrocarbons

Outside the Compressor Station

Revised Addendum to the Summary or Findings Associated with the East Ravine Groundwater Investigation

PG&E Topock Compressor Station, Needles, California

Notes:

1 Residential screening level - residential DTSC CHHSL. If the residential DTSC CHHSL is not established, the USEPA regional screening level is used.

2 ARCADIS. 2008. "Technical Memorandum 3: Ecological Comparison Values for Metals and Polycyclic Aromatic Hydrocarbons in Soil."
May 28. ARCADIS. 2009. "Topock Compression Station - Final Technical Memorandum 4: Ecological Comparison Values for Additional Detected Chemicals in Soil." July 1.

3 CH2M HILL. 2009. "Final Soil Background Technical Memorandum at Pacific Gas and Electric Company Topock Compressor Station, Needles, California." May.

Results greater than or equal to the interim screening level are circled.

NE = not established

USEPA = United States Environmental Protection Agency

DTSC = California Department of Toxic Substances Control

CHHSL = California human health screening levels

Calculations:

BaP equivalent = Sum of Result x TEF, 1/2 reporting limit used for nondetects. If all PAHs are nondetect, the final qualifier code is U.

PAHLow = Sum of Result of low molecular weight PAHs, zero is used for nondetect values.

PAHHigh= Sum of Result of high molecular weight PAHs, zero is used for nondetect values.

-- = not analyzed

µg/kg = micrograms per kilogram

FD = Field Duplicate

ft bgs = feet below ground surface

J = concentration or reporting limit estimated by laboratory or data validation

N = Primary Sample

ND = not detected at the listed reporting limit

TABLE C1-8
Soil Sample Results: Polychlorinated Biphenyls
Outside the Compressor Station
Revised Addendum to the Summary or Findings Associated with the East Ravine Groundwater Investigation
PG&E Topock Compressor Station, Needles, California

Notes:

1 Residential screening level - residential USEPA regional screening levels

2 ARCADIS. 2008. "Technical Memorandum 3: Ecological Comparison Values for Metals and Polycyclic Aromatic Hydrocarbons in Soil."
May 28. ARCADIS. 2009. "Topock Compression Station - Final Technical Memorandum 4: Ecological Comparison Values for Additional Detected Chemicals in Soil." July 1.

3 CH2M HILL. 2009. "Final Soil Background Technical Memorandum at Pacific Gas and Electric Company Topock Compressor Station, Needles, California." May.

Results greater than or equal to the interim screening level are circled.

NE = not established

USEPA = United States Environmental Protection Agency

DTSC = California Department of Toxic Substances Control

CHHSL = California human health screening levels

Total PCBs by Area = Sum of Result of PCBs. Detected values are summed plus ½ the RL for nondetect Aroclors if the Aroclor is detected somewhere in the area.
If all aroclors in a particular sample are nondetect the PCB Total is 0.

-- = not analyzed

µg/kg = micrograms per kilogram

FD = Field Duplicate

ft bgs = feet below ground surface

J = concentration or reporting limit estimated by laboratory or data validation

N = Primary Sample

ND = not detected at the listed reporting limit

TABLE C1-9

Soil Sample Results: Total Petroleum Hydrocarbons and Detected Volatile Organic Compounds

Revised Addendum to the Summary or Findings Associated with the East Ravine Groundwater Investigation

PG&E Topock Compressor Station, Needles, California

Notes:

1 RWQCB. 2008. "Screening For Environmental Concerns at Sites With Contaminated Soil and Groundwater" (Table K-1). May 27.

2 CH2M HILL. 2009. "Final Soil Background Technical Memorandum at Pacific Gas and Electric Company Topock Compressor Station, Needles, California." May.

Results greater than or equal to the RWQCB screening level are bolded.

NE = not established

USEPA = United States Environmental Protection Agency

DTSC = California Department of Toxic Substances Control

RWQCB = Regional Water Quality Control Board

CHHSL = California human health screening levels

TPH = Total Petroleum Hydrocarbon

-- = not analyzed

FD = Field Duplicate

ft bgs = feet below ground surface

J = concentration or reporting limit estimated by laboratory or data validation

mg/kg = milligrams per kilogram

N = Primary Sample

ND = not detected at the listed reporting limit

Notes:

1 Commercial screening level - commercial DTSC CHHSL. If the commercial DTSC CHHSL is not established, the USEPA regional screening level is used.
2 CH2M HILL. 2009. "Final Soil Background Technical Memorandum at Pacific Gas and Electric Company Topock Compressor Station, Needles, California." May.
NE = not established
NA = not applicable
USEPA = United States Environmental Protection Agency
DTSC = California Department of Toxic Substances Control
CHHSL = California human health screening levels
Calculations:
Teq = Sum of Result x TEF, 1/2 reporting limit used for nondetects. If all Dioxins and Furans are nondetect, the final qualifier code is U.
TeqBird = Sum of Result x TEF, 1/2 reporting limit used for nondetects. If all Dioxins and Furans are nondetect, the final qualifier code is U.
TeqMammals = Sum of Result x TEF, 1/2 reporting limit used for nondetects. If all Dioxins and Furans are nondetect, the final qualifier code is U.
-- = not analyzed
FD = Field Duplicate
ft bgs = feet below ground surface
J = concentration or reporting limit estimated by laboratory or data validation
N = Primary Sample
ND = not detected at the listed reporting limit
ng/kg = nanograms per kilogram

Notes:

1 Residential screening level - residential DTSC CHHSL. If the residential DTSC CHHSL is not established, the USEPA regional screening level is used.

2 ARCADIS. 2008. "Technical Memorandum 3: Ecological Comparison Values for Metals and Polycyclic Aromatic Hydrocarbons in Soil."

May 28. ARCADIS. 2009. "Topock Compression Station - Final Technical Memorandum 4: Ecological Comparison Values for Additional Detected Chemicals in Soil." July 1.

3 CH2M HILL. 2009. "Final Soil Background Technical Memorandum at Pacific Gas and Electric Company Topock Compressor Station, Needles, California." May.

Results greater than or equal to the interim screening level are circled.

NE = not established

NA = not applicable

USEPA = United States Environmental Protection Agency

DTSC = California Department of Toxic Substances Control

CHHSL = California human health screening levels

Calculations:

Teq = Sum of Result x TEF, 1/2 reporting limit used for nondetects. If all Dioxins and Furans are nondetect, the final qualifier code is U.

TeqBird = Sum of Result x TEF, 1/2 reporting limit used for nondetects. If all Dioxins and Furans are nondetect, the final qualifier code is U.

TeqMammals = Sum of Result x TEF, 1/2 reporting limit used for nondetects. If all Dioxins and Furans are nondetect, the final qualifier code is U.

-- = not analyzed

FD = Field Duplicate

ft bgs = feet below ground surface

J = concentration or reporting limit estimated by laboratory or data validation

N = Primary Sample

ND = not detected at the listed reporting limit

ng/kg = nanograms per kilogram

Notes:

1 Site background concentration is the 95% upper tolerance limit (UTL) of the elevated percentile from the Steps 3 and 4 Groundwater Background Study Report (CH2M HILL, 2008)

Results greater than or equal to the Background levels are bolded

-- = not analyzed

µg/L = micrograms per liter

J = concentration or reporting limit estimated by laboratory or data validation

ND = not detected at the listed reporting limit

R' = Due to the influence of well construction materials, the results were shown to not be representative of aquifer conditions and were considered to be unusable and rejected

Notes:

1 Site background concentration is the 95% upper tolerance limit (UTL) of the elevated percentile from the Steps 3 and 4 Groundwater Background Study Report (CH2M HILL, 2008)

Results greater than or equal to the Background levels are bolded

-- = not analyzed

µg/L = micrograms per liter

J = concentration or reporting limit estimated by laboratory or data validation

ND = not detected at the listed reporting limit

Notes:

All other parameters analyzed are not detected.

Detected results are bolded

-- = not analyzed

µg/L = micrograms per liter

J = concentration or reporting limit estimated by laboratory or data validation

ND = not detected at the listed reporting limit

R = Result rejected by laboratory or data validation; should not be used for project decision-making.

Notes:

Detected results are bolded

-- = not analyzed

mg/L = milligrams per liter

J = concentration or reporting limit estimated by laboratory or data validation

Deuterium and Oxygen 18 in differences from global standards in ppt

ND = not detected at the listed reporting limit

pH in pH units

Specific conductance in microsiemens per centimeter (µS/cm)

Notes:

Detected results are bolded

Calculations:

-- = not analyzed

pg/L = picograms per liter

J = concentration or reporting limit estimated by laboratory or data validation

ND = not detected at the listed method detection limit

Teq = Sum of Result x TEF, 1/2 reporting limit used for nondetects.

TeqBird = Sum of Result x TEF, 1/2 reporting limit used for nondetects. If all Dioxins and Furans are nondetect, the final qualifier code is U.

TeqMammals = Sum of Result x TEF, 1/2 reporting limit used for nondetects. If all Dioxins and Furans are nondetect, the final qualifier code is U.

Introduction

This Data Quality Evaluation (DQE) report assesses the data quality of soil sample analytical results for the Addendum to the Summary of Findings Associated with the East Ravine Groundwater Investigation, PG&E Topock Compressor Station, Needles, California. Samples were collected and analyzed as requested by the California Department of Toxic Substance Control. The *PG&E Quality Assurance Program Plan* (QAPP) – Topock *Addendum to the PG&E Program Quality Assurance Project Plan for the RCRA Facility Investigation/Remedial Investigation for Soil*, December 2008 and subsequent updates, individual method requirements, internal laboratory quality control (QC) criteria, guidelines from the U.S. Environmental Protection Agency (EPA) Contract Laboratory National Functional Guidelines for Inorganic Data Review, July 2002, and EPA Contract Laboratory National Functional Guidelines for Organic Data Review, October 1999, were used in this assessment.

Analytical Data

Advanced Technology Laboratories (ATL) of Las Vegas, Nevada and Agriculture and Priority Pollutants Laboratories, Inc. (APPL) of Clovis, California performed the required analyses. Both laboratories are certified by the California Department of Health Service's Environmental Laboratory Accreditation Program for the analyses included in Table 2 where appropriate. Samples were analyzed for one or more of the analytes / methods provided in Table 1.

TABLE 1
Analytical Parameters

Parameter	**Method** [a]	**Laboratory**
Dioxin/Furans	SW8290	APPL

Cyanide	SW9014	ATL

[a] SW-846 Test Methods for Evaluating Solid Waste, 3rd Edition, revision 4, 1996.

This DQE report covers 95 normal soil samples, and 8 field duplicate (FD) soil samples. These samples were reported by the laboratories in 15 sample delivery groups identified in Table 1 below:

TABLE 1
Sample Delivery Groups

64191	64322	64816	N005513
N005519	N005597	N005633	N005634
N005648	N005736	N005737	N005817
N005818	N005878	N005879	

The sample delivery groups were assessed by reviewing the following: (1) the chain-of-custody documentation; (2) holding-time compliance; (3) initial and continuing calibration criteria; (4) method blanks and field blanks; (5) laboratory control sample/laboratory control sample duplicate (LCS/LCSD) recoveries; (6) matrix spike/matrix spike duplicate (MS/MSD) recoveries; (7) laboratory duplicate precision; (8) surrogate spike recoveries; (9) internal standard recoveries; (10) FD precision; and (11) the required QC samples at the specified frequencies.

Data flags were assigned as defined in the QAPP. These flags, as well as the reason for each flag, are entered into the electronic database and can be found in Table 3 at the end of this report (sorted by validation reason and then analyte). Multiple flags are routinely applied to specific sample method/matrix/analyte combinations, but there will be only one final flag. A final flag is applied to the data and is the most conservative of the applied validation flags. The final flag also includes matrix and blank sample effects.

The data flags are listed and defined below:

- J = Analyte was present but the reported value might not be accurate or precise (estimated).
- R = Data were unusable due to deficiencies in the ability to analyze the sample and meet QC criteria.

- U = Analyte was not detected at the specified detection limit.
- UJ = Analyte was not detected and the specified detection limit might not be accurate or precise (estimated).

Data Assessment

Data assessment includes a review of the activities described in the following sections.

Holding Times

Holding-time exceedances result in the possible loss of target analytes due to degradation or chemical reactions that usually cause a negative bias to sample results.

Six cyanide (SW9014) samples were extracted outside the EPA recommended holding-time of 14 days. The non-detected results were qualified as estimated and flagged "UJ".

All other holding times were met.

Method Blanks

Method blanks (MB) are used to monitor each preparation or analytical batch for contamination throughout the entire analytical process from sources such as glassware, reagents, instrumentation and other potential contaminant sources within the laboratory. If a target analyte is detected in the method blank, similar detections in the samples are possibly artifacts of laboratory contamination.

Three MBs for dioxins (SW8290) had analytes that were detected at a concentration between the method detection limit (MDL) and the reporting limit (RL). Associated sample results that were at concentrations between the MDL and 5x the associated MB concentration were qualified as non-detect and flagged "U". Sample results greater than 5x the associated MB concentration were qualified, but no flag was applied.

MBs were analyzed at the required frequency; no other target analytes were detected at or above the reporting limit (RL).

Field Blanks

Equipment Blanks (EB) are used to assess the effectiveness of sampling equipment decontamination procedures. Target analytes detected in EBs may indicate that field equipment was not thoroughly decontaminated and/or samples could have been cross contaminated.

Dedicated equipment was used to collect all soil samples and no EBs were required.

Calibration

Initial calibration and periodic verification are essential to generating defensible analytical data. Initial calibrations that do not meet method requirements result in data that may be either positively or negatively biased. Periodic calibration verification ensures that the instrument has not been adversely affected by the sample matrix or other instrument failures that would increase or decrease the sensitivity or accuracy of the method. The

inability to meet initial or continuing calibration analyses may result in qualifying the data as estimated or rejecting the data for project decision-making purposes.

Initial and continuing calibrations were performed as required by the methods. Calibration criteria were met with the following exceptions.

Nineteen volatile samples (SW8260) were associated with continuing calibration verification standards (CCV) that had 2,2-Dichloropropane recover at less than the lower control limit (LCL). The non-detect results were qualified as estimated and flagged "UJ".

Twenty six volatile samples (SW8260) were associated with CCV that had 2-Butanone recover at greater than the upper control limit (UCL). The non-detect results were qualified; no flags were applied.

Twelve volatile samples (SW8260) were associated with continuing CCV that had 2-Hexanone recover at greater than the UCL. The non-detect results were qualified; no flags were applied.

Thirty nine volatile samples (SW8260) were associated with CCV that had Acetone recover at greater than the UCL. The non-detect results were qualified; no flags were applied.

Nineteen volatile samples (SW8260) were associated with continuing CCV that had Acrylonitrile recover at greater than the UCL. The non-detect results were qualified; no flags were applied.

Five PAH samples (SW8270SIM) were associated CCV that had Benzo(b)fluoranthene recover at greater than the UCL. The non-detect results were qualified; no flags were applied.

Internal Standard Recoveries

Internal standards are used for organic analyses and have similar chemical characteristics to the target analytes and provide an analytical response which is distinct from the analyte and not normally subject to interference. The internal standards are added prior to analysis for the purpose of determining analyte concentrations. The internal standard's response is referenced against a relative response factor enabling the sample analyte concentration to be corrected for matrix effects. Internal standard recoveries below 10 percent result in non-detect sample results being rejected.

One volatile sample's (SW8260B) results were associated with an internal standard that recovered at less than LCL. The non-detect results were qualified, however because the bias to a non-detected result based on low recovery would be high; no flags were applied.

All other internal response factors met method acceptance criteria.

Surrogate Recoveries

Surrogates are primarily used in organic chromatography methods and are added prior to sample preparation. The surrogates are added to all samples, standards, and blanks in a preparation batch and provide a measurement to determine recovery for every sample matrix. Surrogate compounds are chosen to represent the various chemistries of the target analytes in a specific method. They are often specified by the method and are deliberately

selected for their improbability of occurring as environmental contaminants. The results are compared to the acceptance criteria as established by the method or the QAPP. Surrogate recoveries below 10 percent result in non-detect sample results being rejected.

Surrogate recoveries met the acceptance criteria with the following exception.

One PCB samples (SW8082) had surrogate recovery less than the LCL. The non-detected results were qualified as estimated and flagged "UJ".

One dioxin samples (SW8290) had a surrogate recovery less than the LCL. The associated non-detected result was qualified as estimated and flagged "UJ".

Matrix Spike Samples

Matrix spike (MS) recoveries are used to evaluate the affect of the sample matrix on the recovery of target analytes. A sample is fortified with a known quantity of a target analyte and is carried through the same preparation and analytical procedures as the unspiked sample. MS recoveries outside the QC limits may indicate that the sample's matrix is affecting the method's ability to accurately quantify the target analyte in the associated sample, or samples from similar locations. A low MS recovery generally indicates a negative bias in the sample data, while a high MS recovery indicates a potential positive bias to the associated sample data. If duplicate MS analyses are performed, a relative percent difference (RPD) greater than QC criteria may further indicate that the sample matrix is affecting the precision of the method for the target analyte that did not meet criteria. Therefore, when the MS does not meet criteria, results are usually considered estimated. MS/matrix spike duplicate (MSD) recoveries below 10 percent result in non-detect sample results being rejected.

MS/MSD acceptance criteria were met with the following exceptions.

Six samples had low biased spike recoveries for one or more of the following metal analytes: Antimony (SW6010B), Arsenic (SW6020A), Cadmium (SW6010B), Chromium (SW6020A), Cobalt (SW6020A), Copper (SW6020A), Lead (SW6010B/SW6020A), Manganese (SW6010B), Molybdenum (SW6010B), Nickel (SW6020A), Selenium (SW6010B/SW6020A), Thallium (SW6010B), and Vanadium (SW6020A). The parent sample non-detected results were qualified as estimated and flagged "UJ" and the parent sample detected results were qualified as estimated and flagged "J".

Four semivolatile samples (SW8270C) had low biased spike recoveries. The non-detected results were qualified as estimated and flagged "UJ" except where the spike recovery was less than ten percent (<10%). Analytes (Benzoic acid and 1,1´-Biphenyl) with non-detect results where the spike recovery was less than 10% were rejected and flagged "R".

One Cyanide (SW9014) sample had low biased spike recovery. The parent non-detected result was qualified as estimated and flagged "UJ".

Six TOCs (SW9060) samples had low biased spike recoveries. The parent detected results were qualified as estimated and flagged "J".

Three TOCs (SW9060) samples had high biased spike recoveries. The parent detected results were qualified as estimated and flagged "J".

One TPH Motor Oil (SW8015B) samples had high biased spike recovery. The non-detect parent sample result was qualified; no flags were applied.

The relative percent differences for one Arsenic (SW6020A) sample MS and MSD exceeded criterion. The detected parent result was qualified as estimated and flagged "J".

Two PAH samples (SW8270SIM) had MS and MSD RPDs that exceeded the criterion. The non-detected parent results were qualified; no flags were applied.

Dilution Test

Dilution Test is used in metals analysis to evaluate matrix interference. The sample concentration must be a minimum of at least 25 times greater than the RL. A fivefold (1+4) dilution is analyzed and must agree within 10 percent of the original concentration. If not, an interference effect must be suspected.

One Copper detect sample result that exceeded the 10 percent RPD criteria was qualified as estimated and flagged "J".

Field Duplicates

Field duplicates (FD) are collected and analyzed to determine if field collection activities or the sample matrix influences the precision of the analytical measurements obtained at the sample site.

All FD acceptance criteria were met with the following exceptions.

Four FD pairs had RPDs greater than the UCL for one or more of the following metals: Barium, Chromium, Nickel, Vanadium, and Zinc (SW6010B). Six FD pairs had RPDs greater than the UCL for TOCs (SW9060). Detected results were qualified as estimated and flagged "J".

Laboratory Duplicates

Laboratory duplicates measure laboratory precision. RPDs that exceed method criteria indicate imprecision in some aspect of the analytical procedure.

The laboratory analyzed duplicate aliquots of field samples at the required frequency. The QC acceptance criteria were met for all methods.

Laboratory Control Samples

A laboratory control sample (LCS) measures laboratory accuracy. Accuracy is the degree of agreement between a measured value and the expected value. The LCS is prepared from laboratory deionized or reagent-grade water and spiked with known amounts of the target analytes of interest. Recovery of analytes outside of QC limits generally indicates a problem with the analytical procedure. A low LCS recovery indicates that the target analyte in associated samples is likely biased low. Likewise, a high LCS recovery indicates that the target analyte in associated samples is likely biased high. Results associated with LCS recovery criteria exceedances are considered estimated. LCS recoveries below 10 percent result in non-detect sample results being rejected.

LCSs were analyzed at the required frequency and were recovered within QC limits with the following exceptions.

Seven semivolatile (SW8270C) samples were associated with LCSs that had recoveries for 1,1´-Biphenyl, 1,2,4,5-Tetrachlorobenzene, Benzaldehyde, Acetophenone , and Hexachlorocyclopentadiene that were between the LCL and 10%. The non-detected sample results were qualified as estimated and flagged "UJ".

Twelve semivolatile (SW8270C) samples were associated with LCSs that had recoveries for 1,1´-Biphenyl that were less than 10%. The non-detected sample results were rejected and flagged "R".

Nineteen volatile (SW8260B) samples were associated with LCSs that had recoveries for Acrylonitrile that were greater than the UCL. The non-detected sample results were qualified; no flags were applied.

Ten semivolatile (SW8270C) samples were associated with LCSs that had recoveries for 3,3´-Dichlorobenzidine that were greater than the UCL. The non-detected sample results were qualified; no flags were applied.

Twenty PAH (SW8270SIM) samples were associated with LCSs that had recoveries for 2-Methylnaphthalene that were greater than the UCL. The detected sample results were qualified as estimated and flagged "J" and the non-detected sample results were also qualified but no flags were applied.

Chain of Custody / Sample Receipt

Samples are collected under chain of custody to ensure that sample integrity is documented and known from the time of collection through receipt at the laboratory where custody is relinquished to the laboratory.

Each sample was documented in a completed chain of custody and received at the laboratory in good condition. All discrepancies identified in laboratory custody were promptly resolved.

Overall Review

The goal of this review is to demonstrate that a sufficient number of representative samples were collected and the resulting analytical data can be used to support the decision-making process. The procedures for assessing the precision, accuracy, representativeness, completeness, and comparability parameters (PARCC) are addressed in the QAPP. The following summary highlights the PARCC findings for the above-defined events:

1. The completeness objective for the PG&E program is 90 % for soil samples. The completeness objectives were met for all method/analyte combinations with the exception of 1,1´-Biphenyl (SW8270C). Although found in natural gas and used as a precursor for the production of PCB's this compound is difficult to analyze and is unlikely to be found in any significant amounts at the Topock Compressor Station. Although all of the 1,1´-Biphenyl results were non-detect, only 36.8 % of the 1,1´-Biphenyl results met the completeness objectives.

2. Samples were collected and analyzed based on approved methods/procedures and the results are reported using industry-standardized units.
3. The routinely acceptable performance of field and laboratory QC indicators (FDs, field blanks, laboratory blanks, LCS, MS/MSD, surrogate, and calibrations) generally show the accuracy and precision of the data meet the project objectives.
    - Six dioxin samples (SW8290) had results that were qualified as not detected due to MB contamination.
    - Six metals samples (SW6010B/SW6020A), four semivolatile samples (SW8270C), one Cyanide sample (SW9014), nine TOCs samples (SW9060), and one TPH Motor Oil (SW8015B) sample were qualified as estimated values due to MS/MSD exceedances.
    - One PCB (SW8082) and one dioxin (SW8290) sample were qualified due to surrogate recovery outside the method criteria.
    - Results from nineteen Volatiles (SW8260) samples were qualified as estimated values due to calibration criteria exceedances for 2,2-Dichloropropane.
4. Results from six cyanide (SW9014) samples were qualified as estimated due to holding time exceedance.
5. Analytical data as qualified meet the data quality objectives and may be used in project decision making with the exception of 1,1´-Biphenyl (SW8270C).

[1] This is the final qualifier flag for this analyte/method combination. If more than one flag was applied, this is the most conservative.

Validation Flags:

J = Analyte was present but the reported value might not be accurate or precise (estimated).

UJ = Analyte was not detected and the specified detection limit might not be accurate or precise (estimated).

R = Data were unusable due to deficiencies in the ability to analyze the sample and meet QC criteria (rejected).

U = Analyte was not detected at the specified detection limit.

Validation Reasons:

CCV<LCL = Continuing calibration recovery less than lower control limit.

CCV<UCL = Continuing calibration recovery greater than upper control limit.

FD>RPD = Field duplicate's relative percent difference is greater than the control limit.

HTp>UCL = Sample extraction holding time exceeded the upper control limit.

IS<LCL = Internal standard recovery, less than lower control limit.

LB>RL = Laboratory blank target concentration greater than the reporting limit.

LCS<LCL = Laboratory Control Sample recovery less than the lower control limit.

LCS>UCL = Laboratory Control Sample recovery greater than the upper control limit.

MS<LCL = Matrix spike recovery less than lower control limit.

MS>UCL = Matrix spike recovery greater than upper control limit.

MSRPD = Relative percent difference between matrix spike and matrix spike duplicate greater than control limit.

SD<LCL = Matrix spike duplicate recovery less than lower control limit.

SD>UCL = Matrix spike duplicate recovery greater than upper control limit.

SerDil = Dilution test is greater than 10% RPD.

Sur<LCL = Surrogate recovery less than lower control limit.

Data Quality Evaluation for Groundwater Analytical Data

Review of Groundwater Analytical Data for the Addendum to the Summary of Findings Associated with the East Ravine Groundwater Investigation, PG&E Topock Compressor Station, Needles, California

Prepared for

Pacific Gas and Electric

November, 2012

CH2MHILL
2525 Airpark Drive
Redding, California 96001

Introduction

This Data Quality Evaluation (DQE) report assesses the data quality of groundwater analytical results for the Addendum to the Summary of Findings Associated with the East Ravine Groundwater Investigation, PG&E Topock Compressor Station, Needles, California, between March 20, 2011 and July 24, 2012. Samples were collected and analyzed as requested by the California Department of Toxic Substance Control. The data was assessed using internal laboratory quality control (QC) criteria; the PG&E Quality Assurance Program Plan (QAPP); the Topock Addendum (July 2008) and subsequent updates.

Analytical Data

Advanced Technology Laboratories (ATL) of Las Vegas, Nevada; Agriculture and Priority Pollutants Laboratories, Inc. (APPL) of Clovis, California; D-TEK Analytical Laboratories, Inc. of Carlsbad California; Sierra Analytical of Laguna Hills, California; TestAmerica Laboratories, Inc. (STL-SEA) of Tacoma Washington; Truesdail Laboratories, Inc. (TLI) of Tustin, California; and Zymax Forensics (Zymax) of San Luis Obispo, California performed the required analyses. All laboratories are certified by the California Department of Health Service's Environmental Laboratory Accreditation Program for the analyses included in Table 2 where appropriate. Samples were analyzed for one or more of the analytes / methods provided in Table 1.

TABLE 1
Analytical Parameters

Parameter	**Method**	**Laboratory**
Dioxin/Furans	SW8290 [b]	APPL
Stable isotopes of deuterium and oxygen	CF-IRMS	Zymax
Hexavalent Chromium	E218.6 [a]	ATL, TLI
Specific Conductivity	E120.1 [a]	ATL
Chloride, Nitrate, Sulfate	E300.0 [a]	ATL
Alkalinity (Carbonate and Bicarbonate)	SM2320 B [c]	ATL
Total Dissolved Solids	SM2540 C [c]	ATL
Suspended Solids	SM2540 D [c]	ATL
Ammonia as Nitrogen	SM4500 NH3 C [c]	ATL
Total Organic Carbon (TOC)	SM5310 C [c]	ATL
Cations	SW6010B [b]	ATL
Metals	SW6020A [b]	ATL, TLI
Mercury	SW7470A [b]	ATL

TABLE 1
Analytical Parameters

Parameter	**Method**	**Laboratory**
Total Petroleum Hydrocarbon (TPH) – Gasoline Range	SW8015B [b]	ATL
TPH-Diesel and Motor Oil Ranges	SW8015B [b]	ATL
Volatile Organic Compounds (VOC)	SW8260B [b]	ATL
Semivolatile Organic Compounds	SW8270C [b]	ATL
Polynuclear Aromatic Hydrocarbons	SW8270-Selected Ion Monitoring [b]	ATL
Pesticides	SW8081A [b]	ATL
PCBs	SW8082 [b]	ATL
Herbicides	SW8151 [b]	ATL, D-TEK, STL-SEA, Sierra

The sample delivery groups were assessed by reviewing the following: (1) the chain-of-custody documentation; (2) holding-time compliance; (3) initial and continuing calibration criteria; (4) method blanks and field blanks; (5) laboratory control sample/laboratory control sample duplicate (LCS/LCSD) recoveries; (6) matrix spike/matrix spike duplicate (MS/MSD) recoveries; (7) laboratory duplicate precision; (8) surrogate spike recoveries; (9) internal standard recoveries; (10) FD precision; and (11) the required QC samples at the specified frequencies.

Data flags were assigned as defined in the QAPP. These flags, as well as the reason for each flag, are entered into the electronic database and can be found in Table 3 at the end of this report (sorted by validation reason and then analyte). Multiple flags are routinely applied to specific sample method/matrix/analyte combinations, but there will be only one final flag. A final flag is applied to the data and is the most conservative of the applied validation flags. The final flag also includes matrix and blank sample effects.

The data flags used defined below:

- J = Analyte was present but the reported value might not be accurate or precise (estimated).
- R = Data were unusable due to deficiencies in the ability to analyze the sample and meet QC criteria.
- U = Analyte was not detected at the specified detection limit.
- UJ = Analyte was not detected and the specified detection limit might not be accurate or precise (estimated).

Data Assessment

Data assessment includes a review of the activities described in the following sections.

Holding Times

Holding-time exceedances result in the possible loss of target analytes due to degradation or chemical reactions that usually cause a negative bias to sample results.

Two herbicide (SW8151) and two semivolatile (SW8270C) samples were extracted outside the EPA recommended holding-time of 7 days. The detected results were qualified as estimated and flagged "J". The non-detected results were qualified as estimated and flagged "UJ".

All other holding times were met.

Method Blanks

Method blanks (MB) are used to monitor each preparation or analytical batch for contamination throughout the entire analytical process from sources such as glassware, reagents, instrumentation and other potential contaminant sources within the laboratory. If a target analyte is detected in the method blank, similar detections in the samples are possibly artifacts of laboratory contamination.

One MB for dioxins (SW8290) had four analytes that were detected at a concentration between the method detection limit (MDL) and the reporting limit (RL) and a second MB had one analyte that was detected at a concentration between the MDL and the RL. The associated sample results were at concentrations between the MDL and 5x the associated MB concentration; those results were qualified as non-detect and flagged "U".

Two MBs for semivolatile (SW8270C) had one analyte (Diethylphthalate) that was detected at a concentration greater than the RL. The associated sample results were at concentrations between the RL and 5x the associated MB concentration; those results were qualified as non-detect and flagged "U".

MBs were analyzed at the required frequency; no other target analytes were detected at or above the reporting limit (RL).

Negative Blanks

Initial calibration blanks (ICBs), continuing calibration blanks (CCBs), and MBs with negative results where the absolute values are greater than the RL can indicate a negative bias in the sample results.

Negative blank results were reported for nickel, aluminum, silver, cobalt, iron, magnesium and beryllium:

- Thirty five associated sample results for nickel (SW6010B) were qualified as estimated. The detect result were flagged "J" the non-detect results were flagged "UJ".
- Twenty seven associated sample results for aluminum (SW6010B) were qualified as estimated. . The detect result were flagged "J" the non-detect results were flagged "UJ".

- Seven associated sample results for silver (SW6010B) were qualified as estimated. The detect result were flagged "J" the non-detect results were flagged "UJ".
- Five associated sample results for cobalt (SW6010B) were qualified as estimated. The detect result were flagged "J" the non-detect results were flagged "UJ".
- Three associated sample results for iron (SW6010B) were qualified as estimated. The detect result were flagged "J" the non-detect results were flagged "UJ".
- Two associated sample results for magnesium (SW6010B) were qualified as estimated. The detect result were flagged "J" the non-detect results were flagged "UJ".
- One associated sample results for Beryllium (SW6010B) were qualified as estimated. The detect result were flagged "J" the non-detect results were flagged "UJ".

Field Blanks

Equipment Blanks (EB) are used to assess the effectiveness of sampling equipment decontamination procedures. Target analytes detected in EBs may indicate that field equipment was not thoroughly decontaminated and/or samples could have been cross contaminated.

Eight hexavalent chromium samples (E218.6) were associated with an EB that had detects greater than the RL, all eight sample results were greater than 5x the associated EB concentration. No flags were applied.

Five chromium samples (SW6020A) were associated with an EB that had detects greater than the RL, four of the five sample results were greater than 5x the associated EB concentration and no flags were applied. One sample result was at a concentration less than 5x the associated EB concentration; that result was qualified as non-detect and flagged "U".

Three toluene samples (SW8260) were associated with an EB that had detects greater than the RL, all three results were at a concentration less than 5x the associated EB concentration; the results were qualified as non-detect and flagged "U".

No other target analytes were detected at or above the reporting limit (RL) in an EB.

Quantitation and Sensitivity

Due to a demonstrated matrix effect for the hexavalent chromium analyses, which is discussed in the "Other" section below, sample interference may require a dilution resulting in elevated RLs for method E218.6 for the non-detected sample results. No flags are applied, but the "ValAdj" reason is noted.

In addition matrix and analyte concentrations resulted in elevated RLs for method E300.0, SW6010B, and SW6020A for the non-detected sample results.

All other method/analyte combinations not mentioned in the Field Blanks or Quantitation and Sensitivity sections met the project RL objectives.

Two sample's hexavalent chromium and chromium results were qualified as estimated and the detected results were flagged "J" due to hexavalent chromium results that exceed the chromium results.

Calibration

Initial calibration and periodic verification are essential to generating defensible analytical data. Initial calibrations that do not meet method requirements result in data that may be either positively or negatively biased. Periodic calibration verification ensures that the instrument has not been adversely affected by the sample matrix or other instrument failures that would increase or decrease the sensitivity or accuracy of the method. The inability to meet initial or continuing calibration analyses may result in qualifying the data as estimated or rejecting the data for project decision-making purposes.

Initial and continuing calibrations were performed as required by the methods. Calibration criteria were met with the following exceptions.

Two herbicide samples (SW8151) were associated with an initial calibration verification standard (ICVS) that had 2,4-DB and Dalapon recover at less than the lower control limit (LCL) and three herbicide samples (SW8151) that were associated with an (ICVS) that had Pentachlorophenol recover at less than the LCL. The non-detect results were qualified as estimated and flagged "UJ".

Two herbicide samples (SW8151) were associated with continuing calibration verification standards (CCV) that had Dalapon recover at less than the LCL. The non-detect results were qualified as estimated and flagged "UJ".

Five volatile samples (SW8260) were associated with a continuing calibration verification standards (CCV) that had 1,1,1-Trichloroethane recovered at less than the LCL. The non-detect results were qualified as estimated and flagged "UJ".

Five volatile samples (SW8260) were associated with a continuing calibration verification standards (CCV) that had Bromomethane recover at less than the LCL. The non-detect results were qualified as estimated and flagged "UJ".

Two volatile samples (SW8260) were associated with a continuing calibration verification standards (CCV) that had 2,2-Dichloropropane recover at less than the LCL. The non-detect results were qualified as estimated and flagged "UJ".

One volatile sample (SW8260) was associated with a continuing calibration verification standard (CCV) that had Chloromethane recover at less than the LCL. The non-detect result was qualified as estimated and flagged "UJ".

One volatile sample (SW8260) was associated with a continuing calibration verification standard (CCV) that had Dichlorodifluoromethane recover at less than the LCL. The non-detect result was qualified as estimated and flagged "UJ".

One volatile sample (SW8260) was associated with a continuing calibration verification standard (CCV) that had Acetone recover greater than the upper control limit (UCL). The detect result was qualified as estimated and flagged "J".

Six semivolatile samples (SW8270C) were associated with a continuing calibration verification standards (CCV) that had Bis(2-chloroisopropyl)ether recover at less than the LCL. The non-detect results were qualified as estimated and flagged "UJ".

Three semivolatile samples (SW8270C) were associated with a continuing calibration verification standards (CCV) that had Benzoic acid recover at less than the LCL. The non-detect results were qualified as estimated and flagged "UJ".

Two semivolatile samples (SW8270C) were associated with a continuing calibration verification standards (CCV) that had 2,4-Dinitrophenol recover at less than the LCL. The non-detect results were qualified as estimated and flagged "UJ".

Five dioxin samples (SW8290) were associated with a continuing calibration verification standards (CCV) that had 1,2,3,6,7,8-Hexachlorodibenzofuran recover at less than the LCL. The non-detect results were qualified as estimated and flagged "UJ".

One dioxin sample (SW8290) was associated with a continuing calibration verification standard (CCV) that had Octachlorodibenzo-p-dioxin recover greater than the UCL. The detect result was qualified as estimated and flagged "J".

One set of hexavalent chromium samples had more than 10 samples between qualifying CCVs; one associated detect result was qualified as estimated and flagged "J".

Internal Standard Recoveries

Internal standards are used for organic analyses and have similar chemical characteristics to the target analytes and provide an analytical response which is distinct from the analyte and not normally subject to interference. The internal standards are added prior to analysis for the purpose of determining analyte concentrations. The internal standard's response is referenced against a relative response factor enabling the sample analyte concentration to be corrected for matrix effects. Internal standard recoveries below 10 percent result in non-detect sample results being rejected.

Three dioxin sample results (SW8290) were associated with an internal standard that recovered at less than LCL. The non-detect results were qualified as estimated and flagged "UJ".

All other internal response factors met method acceptance criteria.

Surrogate Recoveries

Surrogates are primarily used in organic chromatography methods and are added prior to sample preparation. The surrogates are added to all samples, standards, and blanks in a preparation batch and provide a measurement to determine recovery for every sample matrix. Surrogate compounds are chosen to represent the various characterisitics of the target analytes in a specific method. They are often specified by the method and are deliberately selected for their improbability of occurring as environmental contaminants. The results are compared to the acceptance criteria as established by the method or the QAPP. Surrogate recoveries below 10 percent result in non-detect sample results being rejected.

Surrogate recoveries met the acceptance criteria with the following exception.

One TPH-Diesel and TPH-Motor Oil sample (SW8015B) had surrogate recovery greater than the UCL. The detected results were qualified as estimated and flagged "J".

One TPH-Diesel and TPH-Motor Oil sample (SW8015B) had surrogate recovery less than the LCL. The non-detected results were qualified as estimated and flagged "UJ".

Two PCB samples (SW8082) had surrogate recovery less than the LCL. The non-detected results were qualified as estimated and flagged "UJ".

One Herbicide samples (SW8151) had surrogate recovery less than the LCL. The non-detected results were qualified as estimated and flagged "UJ".

One Semivolatile samples (SW8270C) had surrogate recovery less than the LCL. The non-detected results were qualified as estimated and flagged "UJ".

Matrix Spike Samples

Matrix spike (MS) recoveries are used to evaluate the affect of the sample matrix on the recovery of target analytes. A sample is fortified with a known quantity of a target analyte and is carried through the same preparation and analytical procedures as the unspiked sample. MS recoveries outside the QC limits may indicate that the sample's matrix is affecting the method's ability to accurately quantify the target analyte in the associated sample. A low MS recovery generally indicates a negative bias in the sample data, while a high MS recovery indicates a potential positive bias to the associated sample data. If duplicate MS analyses are performed, a relative percent difference (RPD) greater than QC criteria may further indicate that the sample matrix is affecting the precision of the method for the target analyte that did not meet criteria. Therefore, when the MS does not meet criteria, results are usually considered estimated. MS/ matrix spike duplicate (MSD) recoveries below 10 percent result in non-detect sample results being rejected.

MS/ MSD acceptance criteria were met with the following exceptions.

MS/MSD recoveries for twelve samples were less than the LCL for the orthophosphate (E300.0). The parent non-detected results were flagged "UJ".

One Barium (SW6010B) samples had low biased MS/MSD recoveries. The parent detected result was qualified as estimated and flagged "J".

Seven Cadmium (SW6010B) samples had low biased MS/MSD recoveries. The parent non-detected results were qualified as estimated and flagged "UJ".

Two Calcium (SW6010B) samples had low biased MS/MSD recoveries. The parent detected results were qualified as estimated and flagged "J".

Two Cobalt (SW6010B) samples had low biased MS/MSD recoveries. The parent non-detected results were qualified as estimated and flagged "UJ".

Two Copper (SW6010B) samples had low biased MS/MSD recoveries. The parent detected result was qualified as estimated and flagged "J". The parent non-detected result was qualified as estimated and flagged "UJ".

Two Iron (SW6010B) samples had low biased MSD recoveries. The parent non-detected results were qualified as estimated and flagged "UJ".

Two Lead (SW6010B) samples had low biased MS/MSD recoveries. The parent non-detected results were qualified as estimated and flagged "UJ".

One Lead (SW6010B) samples had low biased MS recoveries. The parent non-detected result was qualified as estimated and flagged "UJ".

One Magnesium (SW6010B) samples had low biased MS/MSD recoveries. The parent detected result was qualified as estimated and flagged "J".

One Molybdenum (SW6010B) samples had low biased MS/MSD recoveries. The parent detected result was qualified as estimated and flagged "J".

Two Nickel (SW6010B) samples had low biased MS/MSD recoveries. The parent non-detected results were qualified as estimated and flagged "UJ".

One Potassium (SW6010B) samples had low biased MS/MSD recoveries. The parent detected result was qualified as estimated and flagged "J".

One Chromium (SW6020A) samples had low biased MS/MSD recoveries. The parent detected result was qualified as estimated and flagged "J".

One Copper (SW6020A) samples had low biased MS/MSD recoveries. The parent detected result was qualified as estimated and flagged "J".

One Copper (SW6020A) samples had low biased MS recovery. The parent non-detected result was qualified as estimated and flagged "UJ".

One Copper (SW6020A) samples had zero percent recovery for the MS/MSD. The parent non-detected result was rejected and flagged "R".

One Selenium (SW6020A) samples had low biased MS recoveries. The parent non-detected result was qualified as estimated and flagged "UJ".

One Selenium (SW6020A) samples had low biased MS/MSD recoveries. The parent detected result was qualified as estimated and flagged "J".

One Zinc (SW6020A) samples had low biased MS/MSD recoveries. The parent non-detected result was qualified as estimated and flagged "UJ".

One TPH-Diesel sample (SW8015B) had low biased MSD recoveries. The parent non-detected result was qualified as estimated and flagged "UJ".

One TPH-Gasoline sample (SW8015B) had low biased MS recoveries. The parent non-detected result was qualified as estimated and flagged "UJ".

MS and/or MSD recoveries for 1,2,4-Trimethylbenzene, 1,2-Dibromoethane, 2-butanone, acetone, acrolein, acrylonitrile, bromoform and styrene (SW8260B) were less than the LCL. Eight non-detected parent sample results were flagged "UJ".

One Calcium (SW6010B) samples had high biased MS/MSD recoveries. The parent detected result was qualified as estimated and flagged "J".

Two Potassium (SW6010B) samples had high biased MS/MSD recoveries. The parent detected results were qualified as estimated and flagged "J".

One Sodium (SW6010B) samples had high biased MS/MSD recoveries. The parent detected result was qualified as estimated and flagged "J".

One Barium (SW6020A) samples had low biased MS/MSD recoveries. The parent detected results were qualified as estimated and flagged "J".

One Chromium (SW6020A) samples had high biased MS/MSD recoveries. The parent detected result was qualified as estimated and flagged "J".

The RPD for one Selenium (SW6020A) sample MS/MSD exceeded criterion. The detected parent result was qualified as estimated and flagged "J".

Dilution Test

Dilution Test is used in metals analysis to evaluate matrix interference. The sample concentration must be a minimum of at least 25 times greater than the RL. A fivefold (1+4) dilution is analyzed and must agree within 10 percent of the original concentration. If not, an interference effect must be suspected.

Two Magnesium, one Potassium, three Sodium, and one Zinc (SW6010B) sample had detected results that exceeded the 10 percent RPD criteria. The detected results were qualified as estimated and flagged "J".

Field Duplicates

Field duplicates (FD) are collected and analyzed to determine if field collection activities or the sample matrix influences the precision of the analytical measurements obtained at the sample site.

All FD acceptance criteria were met with the following exceptions.

One FD pair had RPDs greater than the UCL for Nitrate (E300.0). One FD pair had RPDs greater than the UCL for Ammonia (SM4500N H3 C). Two FD pairs had RPDs greater than the UCL for Alkalinity (SM2320 B). One FD pair had RPDs greater than the UCL for Chromium (SW6020A). Three FD pairs had RPDs greater than the UCL for Iron (SW6010B). And One FD pair of dioxins (SW8290) had RPDs greater than the UCL for OCDD, OCDF and 1,2,3,4,6,7,8-HpCDD.

Detected and non-detected results were qualified as estimated and were flagged "J" and "UJ."

Laboratory Duplicates

Laboratory duplicates measure laboratory precision. RPDs that exceed method criteria indicate imprecision in some aspect of the analytical procedure.

The laboratory analyzed duplicate aliquots of field samples at the required frequency. The QC acceptance criteria were met for all methods.

Laboratory Control Samples

A laboratory control sample (LCS) measures laboratory accuracy. Accuracy is the degree of agreement between a measured value and the expected value. The LCS is prepared from

laboratory deionized or reagent-grade water and spiked with known amounts of the target analytes of interest. Recovery of analytes outside of QC limits generally indicates a problem with the analytical procedure. A low LCS recovery indicates that the target analyte in associated samples is likely biased low. Likewise, a high LCS recovery indicates that the target analyte in associated samples is likely biased high. Results associated with LCS recovery criteria exceedances are considered estimated. LCS recoveries below 10 percent result in non-detect sample results being rejected.

LCSs were analyzed at the required frequency and were recovered within QC limits with the following exceptions.

Two LCSs for Carbonate Alkalinity (SM2320 B) had recoveries that were less than the LCL. Twenty associated non-detected sample results were qualified as estimated and flagged "UJ"; one associated detected sample result was qualified as estimated and flagged "J".

One LCS for 2,4,5-T and Dichlorprop (SW8151) had recoveries that were less than the LCLs. Two associated non-detected sample results were qualified as estimated and flagged "UJ".

One LCS for 2,4-Dichlorophenol (SW8270C) had a recovery that was less than the LCL. One associated non-detected sample result was qualified as estimated and flagged "UJ".

One LCS for Acenaphthylene (SW8270SIM) had a recovery that was less than the LCL. One associated non-detected sample result was qualified as estimated and flagged "UJ".

One LCS for 1,2,3,6,7,8-Hexachlorodibenzofuran (SW8290) had a recovery that was less than the LCL. Three associated non-detected sample results were qualified as estimated and flagged "UJ".

One LCS/LSCD pair had RPDs greater than the UCL for 2,4-Dimethylphenol (SW8270C). One LCS/LSCD pair had RPDs greater than the UCL for Hexachlorobutadiene and Nitrobenzene (SW8270C). One LCS/LSCD pair had RPDs greater than the UCL for 1-Methylnaphthalene, 2-Methylnaphthalene, Acenaphthene, Acenaphthylene, Fluorene, and Naphthalene (SW8270 SIM). Non-detected results were qualified as estimated and flagged "UJ".

Two herbicide (SW8151) LCSs were reported with an incomplete list of analytes; the associated detect and non-detect results were qualified as estimated and were flagged "J" and "UJ".

Chain of Custody / Sample Receipt

Samples are collected under chain of custody to ensure that sample integrity is documented and known from the time of collection through receipt at the laboratory where custody is relinquished to the laboratory.

Each sample was documented in a completed chain of custody and received at the laboratory in good condition. All discrepancies identified in laboratory custody were promptly resolved. None were an impact to the data or data quality.

Other

Matrix interference has been encountered at the Topock site, in selected monitoring wells, that affected the sensitivity for hexavalent chromium by the method E218.6. CH2M HILL directed the laboratory to perform additional quality assurance /QC analyses to aid in assessing if there is any effect on method sensitivity for each well location due to the sample matrix.

The laboratory was instructed to analyze an MS of all samples by spiking the samples with 1 µg/L of hexavalent chromium to ensure that identification is accurate for detected results. For non-detected results, the MS should verify there are not false negatives that go undetected.

If the MS is not recovered or the peak is outside of the established retention time window for either detected or non-detected results, the laboratory will make a fivefold dilution of two aliquots of the sample. The first aliquot will be analyzed without the spike, and the second will be spiked with 1 µg/L of hexavalent chromium, and the recovery and peak retention time evaluated. If this MS recovery is not within laboratory QC limits and/or the peak is not within the laboratory retention time window, the laboratory will dilute two additional aliquots of sample tenfold, spike one of the aliquots, analyze the sample/MS, and perform successively greater dilutions of 25:1, 50:1, or 100:1 until the peak identified in the post spike analysis is within the established retention time window for hexavalent chromium, and the recovery of the spike is within laboratory QC limits.

The detected result that is reported by the laboratory on the final data package is chosen from the dilution where both the peak detected in the unspiked and the spiked sample fall within the appropriate retention time and the MS is recovered with QC control limits. The RLs are raised to the level of the appropriate dilution.

For non-detected results, the dilution selected by the laboratory for reporting is taken from the smallest dilution that yields an MS recovery within QC control limits and within the appropriate retention time window.

Confirmation Analysis

When method SW8151 is used to analyze unfamiliar samples, compound identifications should be supported by at least one additional qualitative technique. Second column gas chromatograph/mass spectrometer (GC/MS) criteria appropriate for the qualitative confirmation of compound identifications. Method SW8151suggests GC/MS techniques should be judiciously employed to support qualitative identifications made with this method.

Three samples had detected results for MCPP (SW8151), however the lab did not provide any confirmation data or information. The detected sample results were qualified as estimated and flagged “J”

Overall Review

The goal of this review is to demonstrate that a sufficient number of representative samples were collected and the resulting analytical data can be used to support the decision-making process. The procedures for assessing the precision, accuracy, representativeness, completeness, and comparability parameters (PARCC) are addressed in the QAPP. The following summary highlights the PARCC findings for the above-defined events:

1. The completeness objective for the PG&E program is 95 percent (%) for groundwater samples. The completeness objective was met for all method/analyte combinations.
2. Samples were collected and analyzed based on approved methods/procedures and the results are reported using industry-standardized units.
3. The routinely acceptable performance of field and laboratory QC indicators (FDs, field blanks, laboratory blanks, LCS, MS/MSD, surrogate, and calibrations) generally show the accuracy and precision of the data meet the project objectives.
    - One chromium (SW6020A) and three toluene (SW8260) results were qualified as not detected due to EB contamination.
    - Orthophosphate (E300.0), Barium (SW6010B), Cadmium (SW6010B), Calcium (SW6010B),Cobalt (SW6010B), Copper (SW6010B), Iron (SW6010B), Lead (SW6010B), Magnesium (SW6010B), Molybdenum (SW6010B), Nickel (SW6010B), Potassium (SW6010B), Chromium (SW6020A), Copper (SW6020A), Selenium (SW6020A), Zinc (SW6020A), TPH-Diesel (SW8015B), TPH-Gasoline (SW8015B), 1,2,4-Trimethylbenzene, 1,2-Dibromoethane, 2-butanone, acetone, acrolein, acrylonitrile, bromoform and styrene (SW8260B) samples were qualified as estimated values due to MS/MSD exceedances.
    - TPH-Diesel and TPH-Motor Oil (SW8015B), PCB (SW8082), Herbicide (SW8151) and Semivolatile (SW8270C) samples were qualified due to surrogate recovery outside the method criteria.
    - Herbicide (SW8151), Volatiles (SW8260), Semivolatiles (SW8270C), Dioxin (SW8290) and Hexavalent chromium (E218.6) samples were qualified as estimated values due to calibration criteria exceedances.
4. Results from Two herbicide (SW8151) and two semivolatile (SW8270C) samples were qualified as estimated due to holding time exceedance.
5. Matrix effects were identified in eight samples for hexavalent chromium (E218.6) analyses and the RLs were raised to the concentrations where the matrix effects were overcome as indicated by acceptable MS analyses.
6. Analytical data as qualified meet the data quality objectives and may be used in project decision making.

Table 3A

Data Qualification Summary

East Ravine Groundwater Monitoring Samples

Method	Sample ID	COC Number	Analyte	Units	Final Result	Final Validation Flag[1]	Validation Reason
SW6010B	MW-66BR-270-008	N007165	Magnesium, dissolved	mg/L	0.53	J	CCB>RL
SW6010B	MW-74BR-240-008	N007165	Magnesium, dissolved	mg/L	0.1	UJ	CCB>RL
SW6010B	MW-66BR-270-008	N007165	Nickel, dissolved	ug/L	5	UJ	CCB>RL

[1] This is the final qualifier flag for this analyte/method combination. If more than one flag was applied, this is the most conservative.

Validation Flags:

J = Analyte was present but the reported value might not be accurate or precise (estimated).

UJ = Analyte was not detected and the specified detection limit might not be accurate or precise (estimated).

R = Data were unusable due to deficiencies in the ability to analyze the sample and meet QC criteria (rejected).

U = Analyte was not detected at the specified detection limit.

Validation Reasons:

CCB>RL = Continuing calibration blank target concentration greater than the reporting limit.

CCV<LCL = Continuing calibration recovery less than lower control limit.

CCV<UCL = Continuing calibration recovery greater than upper control limit.

Cr+6>Cr = Hexavalent Chromium concentration greater than the Chromium concentration by a relative percent difference of more than 20 percent .

FD>RPD = Field duplicate's relative percent difference is greater than the control limit.

HTp>UCL = Sample extraction holding time exceeded the upper control limit.

ICB>RL = Initial calibration blank target concentration greater than the reporting limit.

ICVS<LCL = Second source verification standard recovery, less than lower control limit.

IS<LCL = Internal standard recovery, less than lower control limit.

LabA&P = Laboratory accuracy and precision criteria not met.

LB>RL = Laboratory blank target concentration greater than the reporting limit.

LCS<LCL = Laboratory Control Sample recovery less than the lower control limit.

LCSRPD = Laboratory Control Sample duplicate's relative percent difference is greater than the control limit.

MS<LCL = Matrix spike recovery less than lower control limit.

MS>UCL = Matrix spike recovery greater than upper control limit.

MSRPD = Relative percent difference between matrix spike and matrix spike duplicate greater than control limit.

Negative Blank = Blanks with negative results where the absolute values are greater than the RL.

No CF = No confirmation results were provided

NoLCS = No Laboratory Control Sample results were provided for this sample result.

SD<LCL = Matrix spike duplicate recovery less than lower control limit.

SD>UCL = Matrix spike duplicate recovery greater than upper control limit.

SerDil = Dilution test is greater than 10% RPD.

Sur<LCL = Surrogate recovery less than lower control limit.

Sur>UCL = Surrogate recovery greater than upper control limit.

ValAdj = Value reported by laboratory adjusted due to matrix issues.

The Department of the Interior (DOI) and the Department of Toxic Substances Control (DTSC) have reviewed the *Addendum to the Summary of Findings Associated with the East Ravine Groundwater Investigation, Pacific Gas and Electronic Company, Topock Compressor Station, Needles, California* submitted by PG&E on November 15, 2012. While the addendum summarizes the work performed in Phase 2 of the investigation, it was our expectation that the resulting report would expand on the original document and provide a more inclusive evaluation of the combined information from the two phases of the East Ravine - Topock Compressor Station investigation. To that end, we have developed general comments highlighting the main revisions that are expected in the document followed by several focused comments concerning the document identified during our cursory review. It is our expectation that a comprehensive review will occur after the document is revised and provided with the 60% design submittal.

General Comments:

All tables should be expanded to include data from both the Phase 1 and 2 groundwater studies. The table should distinguish between data from each phase using shading or some other format.

Figures 2-1 through 3-5 should show all of the Phase 1 and 2 well numbers and letter identifiers (Add identifiers for Sites A, B, C, C-alt, E, E-alt2, and G).

The text is inconsistent in the use of site terminology and well numbers. The well numbering was sequential with the time of installation and does not facilitate locating the wells in the discussion. The reader is left to continually be looking up well numbers on the map to find out the location of a particular discussion. It would facilitate the review if the text consistently referred to both Site names (Site A, etc) and specific well numbers throughout.

A set of three groundwater results maps are provided, showing only the most recent results and breaking the results up by upper, middle and lower intervals. The maps also depict the entire plume area, rather than focusing on the East Ravine and TCS. The presentation of separate shallow, middle and deep maps for the bedrock wells does not have the utility it did for the alluvial aquifer. Also, presenting only the last round of results masks some higher concentrations that were present in nearly as recent results. It is recommended that PG&E provide a set of groundwater results maps that are focused on the East Ravine and TCS area, provide a separate map for each round of sampling, and depict all depth results on each map.

A figure should be included that provides the results of the soil sampling.

Currently, the ER-TCS report compares only to health-based screening levels. Although this information may be used in the future as part of the Soil RI and Soil Risk Assessment, it should not be focus of the evaluation in the ER-TCS groundwater addendum. It is our expectation that PG&E use the soil work plan DQO (Decision 3 – Impacts to Groundwater) developed for determining a threat to groundwater and that the associated screening levels are used for the comparison and evaluation.

Specific comments noted from preliminary review of report:

Page 1, Summary of Key Findings, Item 1, Figures 3-1 to 3-5.

Cross-section Assessment. Include color coding or contours to depict chromium groundwater concentrations on the cross sections. This will aide in visualizing the extent of contamination and potential source areas.

Extend Cross-Section A-A' in both directions. To the northwest, add MW-24 bench/MW-11 data to extend views of bedrock/alluvial characterization. Suggest adding the MW-40 cluster as it lines up on the section as well. To the south, extend the line to the south to assist in emphasizing that the extent of contamination to the south is unknown.

Add a ross-section parallel to shoreline similar to the physical model to illustrate where contamination does and doesn't reside adjacent to the river.

Move cross-section B-B' to East Ravine proper where well data are concentrated. PG&E concludes on Page 2 that this is the axis of groundwater flow in the area. Include, at a minimum, wells MW-74, MW-70 cluster, MW-58 cluster, MW-57 cluster, and MW-62 cluster.

Figure 3-1: The Phase 2 bedrock contact is not plotted properly in the vicinity of Site 4. Please revise.

Page 1, Summary of Key Findings, Item 2, Groundwater Occurrence in Bedrock

The section concludes that groundwater in bedrock occurs in widely spaced discrete fractures and the bulk rock matrix does not transmit water. Noting this, PG&E should develop an appropriate groundwater model for fractured bedrock and transition to it as part of remedy development and long-term monitoring of the remedy. The continued use of a conventional porous medium model over the lifetime of this project is not appropriate.

Page 2, Summary of Key Findings, Item 3, Refined Extent of Cr(VI) in Groundwater

Include the chromium plume boundary ("blue line" on other PG&E site wide figures) on map views that focus on the East Ravine/Topock Compressor Station (e.g., Figure 1). PG&E should provide some discussion on the plume boundaries especially where the boundary should be dashed/queried. For instance, include text indicating that the extent of contamination south of well MW-60 is not defined. Suggest adding language why PG&E believes that additional characterization is not necessary beyond dashed/queried areas.

Figures 3-6 to 3-8 are at an inappropriate scale as they do not focus on the Compressor Station and East Ravine data. Utilize a scale similar to Figure 3-1 or 3-11 (one inch equals 400' to 500') and move the Compressor Station to near the center of the figure. Are data plotted correctly on Figures 3-6 to 3-8? (e.g., MW-70BR-225 is plotted on the shallow zone figure; MW-67-225 is plotted in the mid-depth; MW-62-110 is plotted as a deep well).

a) East Ravine Area. The section compares bedrock chromium concentration to "background". As background bedrock concentrations do not exist for the Topock site, the text throughout the document should reference the Topock chromium cleanup number of 32 ppb and should provide the rationale for use of the cleanup number as an appropriate limit for bedrock evaluation.

a) East Ravine Area. The section concludes, "The results of the soil samples collected do not suggest a contamination source in the vadose zone". PG&E should assess the source issue comprehensively and look at multiple lines of evidence (e.g., soil data, groundwater data, historic usage, aerial photo interpretations, etc.) in drawing such conclusions which must be supported by sufficient data and evaluation. Furthermore, it is uncertain if the entire AOC 10 data set was evaluated and what type of evaluation was actually conducted in the report.

b) TCS Site. This section should note that the highest chromium concentrations in the Topock area have been detected under the Compressor Station. The section concludes, "…the results of the soil samples collected do not suggest a contamination source in the vadose zone". This statement is currently unsupported as the majority of the soil borings were not well located beneath potential source areas and since the majority of the station has not been characterized for residual soil contamination that may threaten groundwater. With minimal vadose zone data, it is DTSC's position that conclusions regarding potential vadose zone sources cannot be made with any certainty at this time. It is understood that groundwater contamination may suggest a current or historic source of vadose zone contamination.

Page 6, Section 2.4, Monitoring Well Installation and Development: Describe the grout discharge that occurred at the surface away from one well (Site F?) and what was believed to have happened that caused the unusual occurrence.

Page 7, Section 2.5, Borehole Flow Testing: Include the RAS, Inc. hydrophysical testing reports as an attachment to ER/TCS Report.

Page 8, Groundwater Monitoring Well Sampling: Include additional, available groundwater data collected since the November 2012 ER/TCS Report was prepared.

Page 8, Section 2.8, Investigation-Derived Waste Management: The report should discuss the nature and source of the organics contained in the liquids that were treated at LES in Arizona.

Page 9, Section 2.8, Investigation-Derived Waste Management: The report should clarify the nature and source of the organics contained in drill cuttings that were disposed of in Nevada.

Page 13, Section 3.5.1 Distribution of Chromium and Field Measurements: The section begins by mentioning well MW-68-180 and cites the high chromium concentration of 22,000 ppb and that it had lowered in more recent sampling events. It would be important to provide a hypothesis for such changes. Could it be due to sampling method (e.g., different purge volumes or duration), well development, etc.?

Page 14, Section 3.5.2 Sample Results for Nonchromium Contaminants: Figures should be prepared to easily evaluate the distribution of molybdenum, selenium, nitrate, arsenic, and fluoride.

Page 14, Section 3.5.3 Sample Results for Additional Constituents: Evaluate all data including general minerals data. Recall that lower TDS groundwater occurs in shallow wells located within the East Ravine wash proper and may suggest that fresher, cleaner, water has infiltrated and "washed" the shallow zone in the wash area and could explain why the Site F shallow well still exhibits elevated chromium. From a remedy standpoint, this suggests that flushing (or extraction) could work in the East Ravine.

Page 17, Data Quality Evaluation Summary: Include a summary discussion in this section as it currently only references Attachment E.

Page 17, Section 4, Refinements to the Topock Conceptual Site Model: Indicate that the new groundwater data exhibit elevated nitrate under the compressor station and may suggest the station is/was a source.

Summary of March 15, 2013 Call Regarding Agency Comments on Addendum to the Summary of Findings Associated with the East Ravine Groundwater Investigation, Pacific Gas and Electric Company, Topock Compressor Station, Needles, California

Comment No.	Section	Comment	Key Clarification/Resolution Items from March 15, 2013 Call
1		All tables should be expanded to include data from both the Phase 1 and 2 groundwater studies. The table should distinguish between data from each phase using shading or some other format.	None.
2		Figures 2-1 through 3-5 should show all of the Phase 1 and 2 well numbers and letter identifiers (Add identifiers for Sites A, B, C, C-alt, E, E-alt2, and G).	None.
3		The text is inconsistent in the use of site terminology and well numbers. The well numbering was sequential with the time of installation and does not facilitate locating the wells in the discussion. The reader is left to continually be looking up well numbers on the map to find out the location of a particular discussion. It would facilitate the review if the text consistently referred to both Site names (Site A, etc) and specific well numbers throughout.	None.
4		A set of three groundwater results maps are provided, showing only the most recent results and breaking the results up by upper, middle and lower intervals. The maps also depict the entire plume area, rather than focusing on the East Ravine and TCS. The presentation of separate shallow, middle and deep maps for the bedrock wells does not have the utility it did for the alluvial aquifer. Also, presenting only the last round of results masks some higher concentrations that were present in nearly as recent results. It is recommended that PG&E provide a set of groundwater results maps that are focused on the East Ravine and TCS area, provide a separate map for each round of sampling, and depict all depth results on each map.	The group discussed and agreed that average concentrations (with reference minimum and maximum concentrations) should be used to present key water quality constituents since individual events are summarized in the various groundwater monitoring program reports.
5		A figure should be included that provides the results of the soil sampling.	The group confirmed that this figure should focus on samples collected during Phases 1 and 2 of this investigation.
6		Currently, the ER-TCS report compares only to health-based screening levels. Although this information may be used in the future as part of the Soil RI and Soil Risk Assessment, it should not be focus of the evaluation in the ER-TCS groundwater addendum. It is our expectation that PG&E use the soil work plan DQO (Decision 3 – Impacts to Groundwater) developed for determining a threat to groundwater and that the associated screening levels are used for the comparison and evaluation.	The group agreed that discussion of soil data should be kept to high level data presentation of the soil data collected during Phases 1 and 2 of this investigation.

Comment No.	Section	Comment	Key Clarification/Resolution Items from March 15, 2013 Call
7	**Page 1, Summary of Key Findings, Item 1, Figures 3-1 to 3-5**	Cross-section Assessment. Include color coding or contours to depict chromium groundwater concentrations on the cross sections. This will aide in visualizing the extent of contamination and potential source areas.	The group agreed that average concentrations should also be used on the cross-sections.
8		Extend Cross-Section A-A' in both directions. To the northwest, add MW-24 bench/MW-11 data to extend views of bedrock/alluvial characterization. Suggest adding the MW-40 cluster as it lines up on the section as well. To the south, extend the line to the south to assist in emphasizing that the extent of contamination to the south is unknown.	The agencies clarified that the main point of these edits are to show that characterization is not complete to the south.
9		Add a cross-section parallel to shoreline similar to the physical model to illustrate where contamination does and doesn't reside adjacent to the river.	The agencies indicated that the new section should extend from Site I to K to MW-63 to MW-23, and should stop near the extent of the ER-TCS area (i.e., could be ended at MW-22).
10		Move cross-section B-B' to East Ravine proper where well data are concentrated. PG&E concludes on Page 2 that this is the axis of groundwater flow in the area. Include, at a minimum, wells MW-74, MW-70 cluster, MW-58 cluster, MW-57 cluster, and MW-62 cluster.	None.
11		Figure 3-1: The Phase 2 bedrock contact is not plotted properly in the vicinity of Site 4. Please revise.	None.
12	**Page 1, Summary of Key Findings, Item 2, Groundwater Occurrence in Bedrock**	The section concludes that groundwater in bedrock occurs in widely spaced discrete fractures and the bulk rock matrix does not transmit water. Noting this, PG&E should develop an appropriate groundwater model for fractured bedrock and transition to it as part of remedy development and long-term monitoring of the remedy. The continued use of a conventional porous medium model over the lifetime of this project is not appropriate.	The agencies agreed that modifications could be made to the existing groundwater model to address this comment. Text will be added to the document that describes the changes being made to the model based on the findings of the ER-TCS investigation.
13	**Page 2, Summary of Key Findings, Item 3, Refined Extent of Cr(VI) in Groundwater**	Include the chromium plume boundary ("blue line" on other PG&E site wide figures) on map views that focus on the East Ravine/Topock Compressor Station (e.g., Figure 1). PG&E should provide some discussion on the plume boundaries especially where the boundary should be dashed/queried. For instance, include text indicating that the extent of contamination south of well MW-60 is not defined. Suggest adding language why PG&E believes that additional characterization is not necessary beyond dashed/queried areas.	None.
14		Figures 3-6 to 3-8 are at an inappropriate scale as they do not focus on the Compressor Station and East Ravine data. Utilize a scale similar to Figure 3-1 or 3-11 (one inch equals 400' to 500') and move the Compressor Station to near the center of the figure. Are data plotted correctly on Figures 3-6 to 3-8? (e.g., MW-70BR-225 is plotted on the shallow zone figure; MW-67-225 is plotted in the mid-depth; MW-62-110 is plotted as a deep well).	None.

Comment No.	Section	Comment	Key Clarification/Resolution Items from March 15, 2013 Call
15		a) East Ravine Area. The section compares bedrock chromium concentration to "background". As background bedrock concentrations do not exist for the Topock site, the text throughout the document should reference the Topock chromium cleanup number of 32 ppb and should provide the rationale for use of the cleanup number as an appropriate limit for bedrock evaluation.	None.
16		a) East Ravine Area. The section concludes, "The results of the soil samples collected do not suggest a contamination source in the vadose zone". PG&E should assess the source issue comprehensively and look at multiple lines of evidence (e.g., soil data, groundwater data, historic usage, aerial photo interpretations, etc.) in drawing such conclusions which must be supported by sufficient data and evaluation. Furthermore, it is uncertain if the entire AOC 10 data set was evaluated and what type of evaluation was actually conducted in the report.	The group agreed that the soil discussion should be focused on samples collected during Phases 1 and 2 of this investigation, and that conclusions regarding soil should be minimized in this document and left to the Soil RFI/RI.
17		b) TCS Site. This section should note that the highest chromium concentrations in the Topock area have been detected under the Compressor Station. The section concludes, "…the results of the soil samples collected do not suggest a contamination source in the vadose zone". This statement is currently unsupported as the majority of the soil borings were not well located beneath potential source areas and since the majority of the station has not been characterized for residual soil contamination that may threaten groundwater. With minimal vadose zone data, it is DTSC's position that conclusions regarding potential vadose zone sources cannot be made with any certainty at this time. It is understood that groundwater contamination may suggest a current or historic source of vadose zone contamination.	None.
18	**Page 6, Section 2.4, Monitoring Well Installation and Development**	Describe the grout discharge that occurred at the surface away from one well (Site F?) and what was believed to have happened that caused the unusual occurrence.	None.
19	**Page 7, Section 2.5, Borehole Flow Testing**	Include the RAS, Inc. hydrophysical testing reports as an attachment to ER/TCS Report.	Hydrophysical testing reports from both Phases 1 and 2 should be included.
20	**Page 8, Groundwater Monitoring Well Sampling**	Include additional, available groundwater data collected since the November 2012 ER/TCS Report was prepared.	The group agreed that the discussion in the document should be a summary of what we know about Cr, not focused on a single event. Also see Comment 4.

Comment No.	Section	Comment	Key Clarification/Resolution Items from March 15, 2013 Call
21	**Page 8, Section 2.8, Investigation-Derived Waste Management**	The report should discuss the nature and source of the organics contained in the liquids that were treated at LES in Arizona.	None.
22	**Page 9, Section 2.8, Investigation-Derived Waste Management**	The report should clarify the nature and source of the organics contained in drill cuttings that were disposed of in Nevada.	None.
23	**Page 13, Section 3.5.1 Distribution of Chromium and Field Measurements**	The section begins by mentioning well MW-68-180 and cites the high chromium concentration of 22,000 ppb and that it had lowered in more recent sampling events. It would be important to provide a hypothesis for such changes. Could it be due to sampling method (e.g., different purge volumes or duration), well development, etc.?	None.
24	**Page 14, Section 3.5.2 Sample Results for Nonchromium Contaminants**	Figures should be prepared to easily evaluate the distribution of molybdenum, selenium, nitrate, arsenic, and fluoride.	None.
25	**Page 14, Section 3.5.3 Sample Results for Additional Constituents**	Evaluate all data including general minerals data. Recall that lower TDS groundwater occurs in shallow wells located within the East Ravine wash proper and may suggest that fresher, cleaner, water has infiltrated and "washed" the shallow zone in the wash area and could explain why the Site F shallow well still exhibits elevated chromium. From a remedy standpoint, this suggests that flushing (or extraction) could work in the East Ravine.	The agencies clarified that the document should include more discussion of specific conductance data in the ER-TCS area to evaluate trends.
26	**Page 17, Data Quality Evaluation Summary**	Include a summary discussion in this section as it currently only references Attachment E.	None.
27	**Page 17, Section 4, Refinements to the Topock Conceptual Site Model**	Indicate that the new groundwater data exhibit elevated nitrate under the compressor station and may suggest the station is/was a source.	None.

TABLE F-1

DOI Comments on Revised Addendum to the Summary of Findings Associated with the East Ravine Groundwater Investigation

PG&E Topock Compressor Station, Needles, California

Item	Comment Number	Section/Page	Reference Text	60% Design Comment	
General Comments					
1				It is suggested that a table of abbreviations and acronyms be included for reference.	A table of abbreviations and acronyms has been included
Specific Comments – Executive Summary					
2		Executive Summary, Summary of Key Findings, Refined understanding of hydrogeology, Page 1 (Carried forward from 60% design comments.)	"The depth to bedrock beneath the TCS was found to be deeper than previously estimated, which indicates a larger area of saturated alluvium in this area than previously estimated."	Since aquifer thickness has increased, how does this impact the current groundwater remedial program (e.g., well screening zones, water volumes, capture zone, pumping rates, etc.)?	The changes in aquifer thickness as a result of the East Ravine investigation was incorporated into the 60% design. The model was updated to reflect the deeper bedrock along East Ravine and under the compressor station prior the completion of the 60% design document. The revisions to aquifer thickness resulted in only slight changes of the capture zones and pumping volumes.
3		ES, Summary of Key Findings, pg. 2, first paragraph	Based on measurements of specific capacity…	Identify the specific capacity data for the bedrock and unconsolidated materials, parenthetically in the sentence, so the reader can better understand the comparisons.	The sentence has been revised to read "Based on ~~measurements~~ estimates of specific capacity developed from measurements of drawdown during well development and routine well sampling, which provide a qualitative means of comparing the production rate of the different wells, the bedrock produces little groundwater relative to the nearby unconsolidated aquifer (See Attachment B2).
4		ES, Summary of Key Findings, pg. 2, first paragraph	Vertical gradients at well pairs within the saturated bedrock and between the bedrock and unconsolidated aquifer are all upward.	Based on elevated levels of Cr(VI) in MW-70, it appears that in areas of fracture networks that there is vertical migration of Cr(VI) from the unconsolidated to the consolidated aquifers. Thus there are exceptions to the "upward flow" statement. Suggest adding some language to this effect to better clarify the findings. Note: the hydraulic connection between the unconsolidated and consolidated aquifers is further substantiated in Figures 3-2, 3-3, and 3-5 where elevated levels of Cr(VI) are observed in bedrock.	Chromium was likely introduced into the bedrock during the times that water was discharged to East Ravine and is shown in aerial photos to be ponded in two or more places. This ponded water likely reversed the natural upward gradients, pushing chromium into the bedrock and out into the fracture network. The paragraph in question addresses the current conditions, which show persistent and widespread upward gradients from bedrock to alluvium. Hydraulic connection between bedrock and alluvium is part of the conceptual model for this site.
5		Page 3, Summary of Key Findings, Item 2	Hydraulic data collected during this investigation suggest that the groundwater occurrence in the bedrock is within relatively widely spaced, discrete fractures.	The assumption that the fractures are discrete is unsupported by the widespread dissemination of Cr (VI) in East Ravine and TCS areas.	Constituents can travel faster and farther in fractured rock than in porous media of similar permeability, so the extent of the chromium distribution in East Ravine is consistent with a sparsely fractured system, where it appears that ponding of wastewater for a relatively few years was responsible for distributing chromium over a relatively large area. Text has been added that further defines what is meant by a "discrete" fracture, and how Cr can still move throughout the system despite this.
6		Page 3, last paragraph, bulleted items		The bullets are arranged such that it is unclear that bullet 2 & 3 are for the East Ravine and 5-7 are for TCS. It is recommended that the information be reformatted.	The bullets have been reformatted so the intended hierarchy is clear.
Specific Comments – Main Body of Document					
7		Section 1.1, Page 4, 2nd bullet	DOI, Bureau of Land Management (BLM)…	After Bureau of Reclamation notation, change "Bureau" to "Reclamation"	The text has been revised as requested
8		Section 2.0, page 4, First paragraph, Last sentence	Well installation activities were not conducted at contingency Sites 1, I-Alt, or J-Alt.	The listing of site names identified on page 5 shows additional wells (D, E- Alt-1) where no wells were installed. For consistency, the text and table should contain the same information regarding wells not installed.	The text on Page 4 is specific to the Phase 2 investigation work while the table includes both Phase 1 and 2. The sentence has been revised to as follows to clarify that. "During Phase 2 investigations, well installation activities were not conducted at contingency Sites 1, I-Alt, or J-Alt"
9		Section 2.2-Drilling Methods and Lithologic Logging. ..lithologic logs provided in Attachment A-2		Upon review of the bedrock core logs found in Attachment A-2, fractures throughout the cores were characterized as having reddish stains, rust stains, iron stains. Are these stains in response to the presence of iron and is iron forming bacteria a concern with regards to fouling up well screens?	Iron is abundant throughout the alluvial aquifer at the site. The presence of iron in the aquifer materials is very beneficial to the success of in-situ remediation, because as reduced iron is oxidized, Cr(VI) is reduced to Cr(III). This is the basis of the treatment process used at IM-3 and it is expected to be an important part of the in-situ process as well. To date, iron bacteria have not been a problem in wells at the site.

PG&E Topock Compressor Station, Needles, California

<table>
<tr><th>Item</th><th>Comment Number</th><th>Section/Page</th><th>Reference Text</th><th>60% Design Comment</th><th></th></tr>
<tr><td>10</td><td></td><td>Section 2.5, Page 9
(Carried forward from 60% design comments.)</td><td>“The depth-specific samples were collected using a wireline straddle packer tool to isolate fractures in the interval of interest.”</td><td>Please identify the intervals of interest.</td><td>The term “interval of interest” refers to the target zones were samples were collected in each well. This section describes the methods that were used in the investigation. The specific intervals sampled and the sample results are described in Section 3.2</td></tr>
<tr><td>11</td><td></td><td>Section 3.1-Lithology and Hydrostratigraphy</td><td>General Comment</td><td>It is recommended that PG&E prepare geologic cross-sections showing bedrock fractures in each borehole to ascertain if there is a pattern and the possibility of interconnectivity of fractures between boreholes. This information along with pumping test data and groundwater quality data can be utilized to ascertain to what extent fractures throughout the East Ravine are connected (e.g., contaminant pathways).</td><td>The meta-diorite bedrock is highly fractured, consistent with what might expected given the proximity of the detachment fault. However where borehole flow logging has been conducted, the degree of fracturing in the core log was not correlated with the locations of conductive fractures in the boreholes. The individual fractures in the highly fractured zones are typically filled with gouge and secondary minerals. Notations of the degree of fracturing on the core log provide little or no useful information about the permeability of the rock.
To assist with the spatial understanding of where flow zones were identified within the bedrock, these intervals have been added to the cross-sections adjacent the borehole lithology. The following note has also been added to the sections that include boreholes with flow profile information: “Flow zones identified are based on the results of flow profiling within the given borehole. Groundwater flow directions flow within the fractured bedrock cannot be inferred from borehole to borehole given the chaotic nature of the fracture network.”</td></tr>
<tr><td>12</td><td></td><td>Section 3.2-Borehole Flow Characterization Results, pg. 12</td><td>General Comment</td><td>The dominant flow zones in Boreholes MW-60BR-245, MW-70BR-255, and MW-72BR-200 appear to be at or near the same elevations. Could/are these fractures be connected? See table below
<table><tr><th>Bedrock Flow Zone Info</th><th>MW-60BR-245</th><th>MW-70BR-255</th><th>MW-72BR-200</th></tr><tr><td>Dominant Flow Zone Depth</td><td>236-240 fbg</td><td>208 & 220</td><td>148 - 168</td></tr><tr><td>Surface elevation</td><td>555.9</td><td>538.9</td><td>513.5</td></tr><tr><td>Dominant Flow Zone Elevation</td><td>315.9-319.9</td><td>330.9-318.9</td><td>345.5 - 365.5</td></tr><tr><td>Specific Conductivity (Table B-2)</td><td>16,220</td><td>13,030</td><td>17,000</td></tr></table>
Additional data in discussed Section 3.6.1, page 19 (see referenced text below) suggest fracture connections. Please verify.
Reference text:
MW-70BR-225 was pumped for 12 hours and a small drawdown was observed in MW-60BR-245, some 600 feet east of MW-70. Possibly if it was pumped longer drawdown may have been observed in MW-72BR-200.</td><td>There is undoubtedly some degree of connection through the fracture network between many of the wells in the East Ravine, however the overall low permeability of the rock and relatively wide spacing of the wells makes impractical to map the fracture network or define individual fracture connections between boreholes.</td></tr>
<tr><td>13</td><td></td><td>Section 3.2-Borehole Flow Characterization Results, pg. 12, 1st paragraph</td><td>Concentrations were 130 micrograms per liter…</td><td>It is assumed that the reference to concentrations is Cr(VI) concentrations. Please state this for clarification purposes.</td><td>Text has been revised to read: “Concentrations of Cr(VI) were 130 micrograms per liter (µg/L), 290 µg/L, and 78 µg/L in the shallow, middle, and deep samples, respectively.”</td></tr>
<tr><td>14</td><td></td><td>Section 3.2,
Page 12
(Carried forward from 60% design comments.)</td><td>“Depth-specific grab samples were collected from the two primary flow zones using packers.”</td><td>Are the two primary flow zones found at 148-168 feet and 195 feet? If so, this information should be stated parenthetically at the end of the sentence.</td><td>Text has been revised to read: “Depth-specific grab samples were collected from the two primary flow zones (148’ to 168’ and 191’ to 198.5’) using packers.</td></tr>
<tr><td>15</td><td></td><td>Section 3.4, Page 14</td><td>For the purpose of this report, where analysis of the soil data is focused on the development of the conceptual site model for the ER-</td><td>The introduction text in Section 3.4 notes that concentrations were only “compared only to BTVs”. The comparison should also include reporting limits.</td><td>The text has been revised to read: “For the purpose of this report, where analysis of the soil data is focused on the development of the conceptual site model for the ER-TCS areas, results for inorganic analytes are compared only to BTVs. For organic analytes, results inside the compressor station fence line were compared to commercial screening levels and results outside the fence line</td></tr>
</table>

TABLE F-1
DOI Comments on Revised Addendum to the Summary of Findings Associated with the East Ravine Groundwater Investigation
PG&E Topock Compressor Station, Needles, California

Item	Comment Number	Section/Page	Reference Text	60% Design Comment	
			TCS areas, results are compared only to BTVs.		were compared to residential screening levels. If the appropriate DTSC CHHSL was not established, the USEPA regional screening level was used." Reporting limits for all compounds are listed in the tables in Appendix C.
16		Section 3.4, Page 14	For the purpose of this report, where analysis of the soil data is focused on the development of the conceptual site model for the ER-TCS areas, results are compared only to BTVs.	The introduction text in Section 3.4 notes that concentrations were only "compared only to BTVs". One would presume that part of the conceptual site model would be defining the source and include transport of contaminants from the soil to groundwater. Were comparison values considered for impacts to groundwater and if not, when will they be considered? As stated in previous comments, it is our expectation that PG&E use the soil work plan DQO (Decision 3 – Impacts to Groundwater) developed for determining a threat to groundwater and that the associated screening levels are used for the comparison and evaluation.	The analysis of impacts to groundwater from soil contaminants will be developed in Volume 3 of the RFI.
17		Section 3.4.1, Page 15, Site 5	Barium, cobalt, copper, lead, nickel, vanadium and zinc were also detected above the BTV, and none of the detected concentrations exceeded respective commercial screening levels.	The introduction text in Section 3.4 notes that concentrations were only "compared only to BTVs". Delete the segment of the sentence "and none of the detected concentrations exceeded respective commercial screening levels".	The sentence has been revised as requested.
18		Section 3.4.1, Page 15, Site 6	Lead was also detected above the BTV but not the commercial screening levels.	The introduction text in Section 3.4 notes that concentrations were only "compared only to BTVs". Delete the reference to "commercial screening levels".	The sentence has been revised as requested.
19		Section 3.4.2, page 15		The introduction text in Section 3.4 notes that concentrations were only "compared only to BTVs" yet screening levels are discussed in this section. Please address the inconsistency.	See response to comment 15 above, which clarifies that commercial screening levels were used for organic compounds where no BTV has been established.
20		Section 3.5.1-Distribution of Chromium and Field Measurements, pg. 16, Second paragraph	…..the existing monitoring wells do not fully define the extent of the elevated Cr(VI) in bedrock to the south of the East Ravine.	MW-65-160 and 225 well cluster show elevated Cr(VI) concentrations as so does MW-66-230 and 165. This data suggests that the western boundary is also not fully defined. Further, as the "Old Well" is located between MW-10 and MW-38 and was historically used as an injection well, this could further complicate Cr(VI) plume delineation within bedrock.	The MW-65-160 and 225 and MW-66-165 and 230 wells area all completed in the alluvium and don't provide any information about the delineation of Cr(VI) in bedrock. Cr(VI) was ND in the bedrock well at MW-66 cluster (MW-66BR-270). There is no bedrock well at the MW-65 cluster. Considering that the "Old Well" was intended to provide a relatively modest water supply for the construction of the compressor station and that the alluvial aquifer in this area provides ample water of reasonable quality, there would have been no reason to extend the well to bedrock. In addition, it was likely drilled with the cable-tool drilling equipment common in that era, which would have not been able to penetrate far into competent bedrock. The total depth of the well has been verified to be 158 feet below ground surface, which is approximately where the top of bedrock is estimated for this area based on boring logs from adjacent wells. For example, the boring log for the MW-38 location, which is about 170 feet to the north was drilled to 195 feet below ground surface, where loosely consolidated bedrock was logged from approximately 178 feet bgs. Bedrock shallows to the south toward the mountain front; therefore, bedrock is estimated to be slightly shallower at the "old well" (TCS-4).
21		Section 3.5.1, Page 16, 2nd full paragraph	It is therefore unlikely that the plume extends any great distance to the south beyond the existing well network.	"Any great distance" is a relative term, depending on the circumstances and personal interpretation. It would be appropriate to reference the extent of the plume relative to estimated boundary shown in Figure 3-8.	The sentence has been revised to read: "It is therefore unlikely that the plume extends ~~any great distance to~~ the south beyond the inferred plume boundary shown on Figure 3-8.~~existing well network~~.
22		Section 3.5.2-Sample Results for Non-Chromium Contaminants of Potential Concern in the ER-TCS Wells, pg. 17	Nitrate – Average nitrate concentrations above the UTL of 5.03 mg/l were found in eleven wells, while concentrations above the California MCL of 10 mg/l were found in eight wells on the compressor station, with higher concentrations generally in shallower wells.	Does the ground water with high concentrations of nitrate require any special handling or disposal?	Nitrate is more easily reduced than Cr(VI), so it will be eliminated in the IRZ line and in any of the IRL/TCS wells where carbon is added (water extracted from the East Ravine area will be re-injected using the TCS injection wells). There is no plan to pump water from below the compressor station, so it is not anticipated that any large volumes of water with elevated concentrations of nitrate would be generated during the remedial action. The purge water from these wells (generated during sampling) is currently managed at IM-3, where the process used to reduce Cr(VI) also reduces nitrate.

DOI Comments on Revised Addendum to the Summary of Findings Associated with the East Ravine Groundwater Investigation

PG&E Topock Compressor Station, Needles, California

Item	Comment Number	Section/Page	Reference Text	60% Design Comment	
23		Section 3.5.2-Sample Results for Non-Chromium Contaminants of Potential Concern in the ER-TCS Wells, pg. 17	Selenium – Maximum concentrations exceeded alluvial aquifer background in both the deep and shallow wells in the MW-60 cluster and in the shallower well at the MW-64 cluster	What are the maximum concentrations and were they above the California MCL of 50 ug/l? Will groundwater containing Selenium above the California MCL of 50 ug/l require any special handling?	As shown on Figure 3-11, selenium above the MCL of 50 ug/L was detected only in wells MW-67-185 and MW-67-225. It is not anticipated that this water would require any special handling.
24		Section 3.6.1, Page 19, 1st paragraph (Carried forward from 60% design comments.)	"The drawdown caused by pumping was too small to observe directly in any but the closet well, MW-70-105 9shallower well pair to the pumping well), where the well exhibited a consistent dewatering trend and a total of 1.6 feet of drawdown . . . "	What is the distance from the pumping well to well MWE-70-105?	The distance is approximately 15 feet.
25		3.6.1-Constant Rate Extraction Testing, pg. 19, second full paragraph	General comments on paragraph	With regards to seeing no drawdown effects on alluvial well MW-59-100, given the short time period the pump test was run it may be that the test was not run long enough to have any influence on water levels at MW-59-100 The statement that "relatively high flow rates, the elevated chromium concentrations, and the stable isotope signature showing a mixture of bedrock and alluvial water at MW-70-225 are all consistent with the theory that this well may be drawing water from the alluvium well through a bedrock fracture system" suggests that there are contaminate pathways from the alluvial aquifer to the bedrock aquifer. Interconnectivity between the alluvial aquifer and the bedrock aquifer by way of bedrock fracture systems provide a window for contaminate migration. Although there is an upward flow component from the bedrock aquifer to the alluvial aquifer, mounding caused by injection wells may induce vertical flow from the alluvial aquifer into the bedrock aquifer in areas of fracture systems, possibly causing cross-contamination. The proposed locations of injection wells TCS-1 and TCS-2 are in the vicinity of the "old well" (possible source area) and MW-70BR (possible bedrock fracture zone). Possible mounding effects might result in cross-contamination. Discuss how the groundwater remedial program addresses groundwater contamination in bedrock.	Agreed. A longer pump test might have shown drawdown in the alluvium. Hydraulic connection between the alluvium and the bedrock is likely. The TCS injection wells will be injecting water amended with carbon, so if that water moves into bedrock, it will be remediating Cr(VI) as it moves. The design of the groundwater remediation systems, including those components of the system designed for the East Ravine, is provided in the 60% design report, and has been updated in the 90% design.
26		Section 3.6.2, Page 19 (Carried forward from 60% design comments.)		Please identify the range of specific capacity measurements so readers can better understand the specific capacity estimates without having to refer to data located elsewhere in the document.	The text has been revised as follows "The higher specific capacity (typically greater than 3 gpm/ft) is observed in the alluvial wells. Several of the bedrock wells pump dry, precluding measurement of specific capacity. The bedrock well with the highest specific capacity (averaging about 2.8 gpm/ft) is MW-69-195, located on the TCS. MW-69-195 is a shallow zone well with 20 feet of screen just below the water table in bedrock. The second-highest bedrock specific capacity (averaging about 0.6 gpm/ft) was observed at well MW-70BR-225, where the constant rate pumping test was conducted.
27		3.6.2-Specific Capacity Estimates, pg. 19	MW-69-195 is a shallow zone well with 20 feet of screen just below the water table in bedrock.	Could MW-69 also represent another fracture zone where water from the alluvial aquifer could be migrating into the bedrock aquifer?	Yes. Both the high specific capacity of MW-69-195 relative to other bedrock wells and the isotopic signature of the water suggest that a connection to the alluvial aquifer, however the dominance of upward gradients between bedrock and overlying alluvium would tend to limit downward migration of constituents into bedrock.
28		4.0-Refinements to the Topock Conceptual Site Model, pg. 21-22, last sentence on pg. 21	"Lithologic data collected during the installation of these wells provide better definition of the topography of the bedrock contact below the TCS and, as a result, indicate a larger area of saturated alluvium beneath the TCS that previously estimated"	Has a bedrock topographic map been generated for the site?	A contour map of the elevation of the top of bedrock was included in the RFI Volume 2 (Figure 5-9), however the contours near the compressor station do not reflect the more recent data from the East Ravine investigation.

TABLE F-1
DOI Comments on Revised Addendum to the Summary of Findings Associated with the East Ravine Groundwater Investigation
PG&E Topock Compressor Station, Needles, California

Item	Comment Number	Section/Page	Reference Text	60% Design Comment	
29		Section 4.0, Page 22, 1st partial paragraph	Based on the data from MW-66BR-270 and MW-68BR-280, concentrations of the Cr(VI) in the alluvium do not extend in to the bedrock directly beneath the TCS.	It would appear that, when considering concentrations in MW-69-195, MW 65-225, and MW-70BR-225, a more appropriate statement would be that "concentrations of the Cr(VI) in the alluvium do not extend in to the bedrock directly beneath the *northern half* of the TCS*, but may be present in the southern portion.*"	MW-65-225 is an alluvial well and MW-70BR-225 is not beneath the compressor station. The text has been revised as follows: "Based on the data from MW-66BR-270 and MW-68BR-280, concentrations of Cr(VI) in the alluvium do not extend into the bedrock directly beneath the TCS. Concentrations of Cr(VI) are observed in ~~the~~ bedrock well MW-69-195 immediately south of the TCS fence line where saturated alluvium is not present, but Cr(VI) has not been detected in the southern most bedrock well MW-74-240.
30		4.0-Refinements to the Topock Conceptual Site First full paragraph	…do not suggest any previous unknown hotspots or contaminate sources	Information from the "old well" investigation may result in additional source information. This should be considered in the conceptual site model before such a conclusion is made.	The old well is in a known source location, the former infiltration ponds. Since the old well does not extend deep into bedrock, if at all, it would make little difference to the conceptual model whether Cr(VI) was released to the ponds or to this old well.
31		4.0-Refinements to the Topock Conceptual Site Model, pg. 22, 1st paragraph	"The data suggests a localized connection to the alluvium rather that to some as yet undiscovered zone of highly fractured and more permeable bedrock".	A review of Boring Logs – BH-69 and BH-70 provide the following information with regards to fractures:	The meta-diorite bedrock is highly fractured, consistent with what might expected given the proximity of the detachment fault. However where borehole flow logging has been conducted, the degree of fracturing in the core log was not correlated with the locations of conductive fractures in the boreholes. The individual fractures in the highly fractured zones are typically filled with gouge and secondary minerals. Notations of the degree of fracturing on the core log provide little or no useful information about the permeability of the rock.

				225-230	Highly Fractured
				232-234	Highly Fractured
				236-238	Highly Fractured
				Does the data suggest that fracturing might be more widespread then otherwise believed?	
32		Section 4.0, Page 22, 2nd paragraph	The conceptual model suggested by the hydrophysical logging is that the groundwater flow occurs in relatively widely spaced discrete fractures.	The assumption that the fractures are discrete is unsupported by the widespread dissemination of Cr (VI) in East Ravine and TCS areas.	See response to comment 5.
33		4.0-Refinements to the Topock Conceptual Site Model, pg. 22, 3rd paragraph	"In fractured crystalline rock, typical mobile porosity is 1% or less"	Based on the information collected by PG&E, mobile porosity may be more than 1% in some localized areas. Can the model take this into account?	The model can accommodate any mobile porosity value.
34		Section 4.0, Page 22, Footnote		DOI Comment 18 on the 30% design states "The statement that "bedrock in East Ravine has relatively few conductive fractures" is broad and not well supported as evidenced by the extent of the plume and conductivity of some of the wells." These two paragraphs do not address the extent of the plume found in the East Ravine area.	Constituents can travel faster and farther in fractured rock than in porous media of similar permeability, so the extent of the chromium distribution in East Ravine is consistent with a sparsely fractured system, where it appears that ponding of wastewater for a relatively few years was responsible for distributing chromium over a relatively large area.

DTSC Comments on Revised Addendum to the Summary of Findings Associated with the East Ravine Groundwater Investigation

Comment Number	Comment Number	Section/Page	Reference Text	60% Design Comment	PG&E Response to Comment
1				As the Technical Memorandum (TM) is 958 pages long, please revise it to include a Table of Contents.	Agree
2		Executive Summary, Page 1, Item 2.	"…is consistent with the existing conceptual site model for the East Ravine area."	The existing conceptual site model for the East Ravine and Compressor Station area should be included in the document (suggest Section 4). Present what PG&E believes is the conceptual model, including supporting illustrations. PG&E should also identify the uncertainties and assumptions made as part of the conceptual model.	Text has been added to Section 4 to more clearly present the current conceptual model for bedrock under the East Ravine and the TCS.
3		Executive Summary, Page 2, Item 3b.	Low levels of Cr(VI) were found where the water table occurs in bedrock at the southern edge of the TCS, but were not detected at the southernmost location (Site J, MW-74-240).	Minor edit. Need to add "the" and a comma.	Agree.
4		Executive Summary, Conclusion, Page 2, Paragraph 1.	Based on data collected during Phase 2 of this ER-TCS investigation, the refined conceptual site model confirms what was inferred based on previously available data (and described in the *2009 Summary of Findings Associated with the East Ravine Groundwater Investigation Report* [CH2M HILL, 2009a]), that assumptions associated with the anticipated design and operation of the final groundwater remedy do not need to be modified.	Revision of this sentence appears necessary as the remedy design was modified, although not significantly, based on the results of the Phase 2 investigation (e.g., extraction at the Site H area was added due to yield and depth of contamination). Similar language is found in the second to last paragraph of Section 4.	The sentence in question will be revised to read: ~~"Based on~~ Data collected during Phase 2 of this ER-TCS investigation have resulted in the addition of two alluvial aquifer injection wells near the compressor station and a bedrock extraction well near MW-70 to the remedial design. However the data from the Phase II investigation ~~the refined conceptual site model confirms what was inferred based on previously available data (and described in the 2009 *Summary of Findings Associated with the East Ravine Groundwater Investigation Report* [CH2M HILL, 2009a]),~~ that the overall ~~assumptions associated with the anticipated~~ design ~~and operation~~ of the final groundwater remedy in the East Ravine, which relies on pumping from the bedrock, does not need to be modified." Similar revision will be made to the relevant text in Section 4.
5		Executive Summary, Conclusion, Page 2, Paragraph 2.	As communicated by the Department of Toxic Substances Control (DTSC) in a May 10, 2012, email (DTSC, 2012), Phase 2 field investigation activities are complete with the exception of Site H (MW-70 well series), where the agencies have directed PG&E to conduct additional characterization to determine the vertical extent of Cr(VI) in groundwater. This work and any further well installation will be considered as part of the groundwater monitoring program to be established as part of the groundwater remedy.	DTSC does not believe that the investigation activity specified in the cited text was captured in the 60% design. PG&E needs to make sure that this item is addressed during preparation of the 90% design and address what is meant by "will be considered as part of the groundwater monitoring program?"	Additional investigation to characterize the vertical extent of contamination at the MW-70 location will be described in the 90% design document. The statement "will be considered as part of the groundwater monitoring program" was meant to confirm that this investigation is not intended to precede and thereby delay the remedial design, but rather be considered as part of the groundwater monitoring program that will be implemented in conjunction with the installation of the remedy.
6		3.1 Lithology and Hydrostratigraphy, Page 11	Saturated alluvium in the East Ravine area was only encountered at MW-71-035 (Site L), where the saturated thickness above conglomerate bedrock was relatively thin. Sediments at this location were relatively finegrained compared with areas of saturated sediments to the east.	Clarification/revision needed. The cited sentence can be interpreted to indicate that the only saturated East Ravine alluvium is located at well MW-71 and is relatively thin. Please revise to clarify that this is not the case (e.g., Site G/MW-59, MW-70).	In fact, the only place that saturated alluvium has been encountered is at well MW-71. The alluvial wells were installed just above bedrock at MW-59 and MW-70 locations have been dry except for a brief period shortly after they were installed. The water that was initially in these wells was likely introduced during drilling. The sentence is correct in stating that MW-71 is the only place that saturated alluvium has been encountered in East Ravine.

7		3.4.2 Summary of TPH and Organics Results, Page 15	Calculated quantities of dioxins and furans (toxicity equivalents quotient [TEQ]) were below respective screening levels at all sites where fill was encountered including Site 1, BH-67, BH-68, BH-65, BH-66, and BH-69 (dioxins and furans were not analyzed at BH-70 as fill was not encountered).	Table C1-11 indicates that some levels exceeded interim screening levels. Please revise.	The text will be revised to read: Calculated quantities of dioxins and furans (toxicity equivalents quotient [TEQ]) were below the Human-TEQ screening value of 50 ng/kg ~~respective screening levels~~ at all sites where fill was encountered including Site 1, BH-67, BH-68, BH-65, BH-66, and BH-69 (dioxins and furans were not analyzed at BH-70 as fill was not encountered). However, the 0 – 0.5 feet bgs sample from BH-69 exceeded the TEQ-Avian and TEQ-mammal ecological screening values (ECVs) and the 2 to 3 feet bgs sample from BH-69 exceeded the TEQ-Mammal ECV. No other samples exceeded the ECVs.
8		3.4.2 Summary of TPH and Organics Results, Page 15	Volatile organic compounds were not detected in any of the samples collected with the exception of the surface soil sample at BH-70 where 4-isopropyl toluene was detected below the screening level.	Table C1-9 indicates that isopropyl benzene was also detected at 60 feet bgs at BH-67. Please revise.	The sentence will be revised to read: "Volatile organic compounds were not detected in any of the samples collected with the exception of the surface soil sample at BH-70 where 4-isopropyl toluene was detected and the sample from 60 feet in BH-67 where isopropyl benzene was detected. ~~below the screening level.~~"
9		3.7.2 Soil Data Quality Evaluation Summary, Page 21	**3.7.2 Soil Data Quality Evaluation Summary**	Need to change "Soil" to "Groundwater" in 3.7.2 heading.	Heading will be changed to read: **"Groundwater Data Quality Evaluation Summary"**
10		4.0 Refinements to the Topock Conceptual Site Model, Page 22	Elevated concentrations of Cr(VI) are observed in the saturated alluvium beneath the TCS with concentrations in the parts per million on the north and east sides of the TCS; however, these data are not unlike concentrations previously observed to the north and northeast of the TCS.	This statement should probably be revised to reflect that the highest concentrations of Cr(VI) that have been detected on the site were found in the alluvial aquifer beneath the TCS (see page 2 of the document). The section should also discuss how this changes the general understanding of where the core of the plume occurs at the site. Prior to the ER/TCS investigation, the hot spot was off site at MW-20 Bench. The ER/TCS investigation changes the conceptual model in that the core/highest concentrations of the Cr(VI) plume is more extensive than previously understood.	The text will be revised to read: "The highest concentrations of Cr(VI) yet detected at the site are observed in the saturated alluvium beneath the TCS, within an area of elevated concentrations in the parts per million along the north and east sides of the TCS. Although these concentrations are not unlike concentrations previously observed to the north and northeast of the TCS, it does appear that the area of elevated concentrations around the compressor station is larger than previously understood during the 30% design. This finding has been taken into account in the subsequent phases of the design by adding two carbon amended injection wells (TCS-1 and TCS-2) to accelerate remediation of Cr(VI) in the alluvium under the TCS."
11		4.0 Refinements to the Topock Conceptual Site Model, Page 22	With the exception of concentrations detected in the parts per million at MW-70BR-225, Cr(VI) concentrations observed in the new wells are similar to the previously installed wells and do not suggest any previously unknown hotspots or contaminant sources.	Please revise the cited sentence to mesh with the text on page 15/16 of the TM that suggests a source near well MW-68-180. See also comment above.	The text will be revised to read: "With the exception of concentrations detected in the parts per million at MW-70BR-225, Cr(VI) concentrations observed in the new wells are similar to the previously installed wells and do not suggest any previously unknown hotspots or contaminant sources outside the compressor station, which was always considered a potential source location."
12		Figure 3-1	Bedrock/Alluvial Aquifer Phase 2 contact line.	Shouldn't the cited contact pass right through Site H/MW-70 and lie on the other side (east) of Site L /MW-71?	This estimated contact line has been corrected such that it is to the east of MW-71-35. Saturated alluvium was not encountered at the Site H/MW-70 location. It is acknowledged that the shallow screen, as shown on Figure 3-2 (cross-section A-A') is slightly confusing given the projection of the well screen relative the water table. The depth to rock at this location was logged at 68.5 feet below ground surface (approximately 471.5 feet above mean sea level) and the average water level that this contact is based on is 456 feet above mean sea level. Therefore, the contact should pass slightly north of MW-70, as shown. Figure 3-2 has been revised to show the shallow screen and projected alluvium/bedrock/water table contact more precisely.

TABLE F-2

DTSC Comments on Revised Addendum to the Summary of Findings Associated with the East Ravine Groundwater Investigation

Comment Number	Comment Number	Section/Page	Reference Text	60% Design Comment	PG&E Response to Comment
13		Figure 3-3		Please modify cross-section B-B' as follows: MW-62 shows alluvium occurring beneath the conglomerate.	The figure will be corrected to show conglomerate to total depth in MW-62.
14		Figure 3-6		Please modify cross-section E-E' as follows: Move the section line to pass directly through MW-21 and MW-73-80. This will bring all existing wells very close to the line. Then project wells MW-71-35, MW-62 cluster and MW-72 cluster onto the line. DTSC requested this section to illustrate where contamination approaches the river.	The cross section will be modified as requested.

Appendix M
Addendum to Freshwater Pre-Injection Treatment System Conceptual Design Basis Memorandum

Addendum to Freshwater Pre-injection Treatment System Conceptual Design Basis PG&E Topock Compressor Station, Needles, California

PREPARED FOR: Pacific Gas and Electric Company

PREPARED BY: CH2M HILL

DATE: August 28, 2014

1.0 Introduction

Since the submittal of the 60% design of the Pacific Gas and Electric Company (PG&E) Topock Compressor Station (TCS) (CH2M HILL 2013), the State Water Resources Control Board (State Board) has issued a decision letter on November 20, 2013, and the California Department of Toxic Substances Control (DTSC) has provided direction in its comment on the 60% design (#145 DTSC-50) that will include an arsenic pre-treatment contingency as part of the 90% design. In compliance with this DTSC directive, this technical memorandum (TM) presents the design basis for a potential future pre-treatment option for freshwater.

This option assumes that the primary source is groundwater from well HNWR-1A and the secondary source is groundwater from wells HNWR-1 or Site B. All three freshwater supply wells are located in Arizona. This assumption will be revisited after completion of the alternative freshwater source evaluation—the field work is currently under way. The potential future treatment system, referred to herein as the freshwater pre-injection treatment system (FWPTS), will be located in the vicinity of the planned remedy-produced water-conditioning plant. All components of the FWPTS are located on previously disturbed areas within the PG&E-owned parcel.

The treatment goals of the FWPTS are arsenic removal to concentrations less than the federal and California maximum contaminant level (MCL) of 10 micrograms per liter (µg/L) (California Department of Public Health, 2013). This TM discusses the evaluation of available treatment technologies for arsenic; the selection of technologies for bench-scale testing; the results from bench-scale testing at CH2M HILL's Applied Science Laboratory (ASL) in Corvallis, Oregon; and the design basis/design criteria for the FWPTS. This document also includes a process flow diagram, a preliminary equipment layout, and a preliminary list of key equipment.

The design information presented herein has been developed based on Topock-specific information (that is, bench-scale testing results of HNWR-1 water) and experience in designing and operating arsenic groundwater treatment systems on non-Topock projects. Because of its location, the potential future FWPTS will be designed to achieve a safe, harmonious, and sustainable operation within TCS. Engineering design details of the FWPTS are included in the 90% design.

2.0 Freshwater Water Quality, Treatment Goals, and Design Flow Rates

For the purpose of this conceptual design, it is assumed that the water quality from the future supply well (HNWR-1A) in Arizona is similar to that of the HNWR-1 well. PG&E has collected and analyzed six samples from HNWR-1 starting in November 2010. Analytical results from November 2010 through February 2014 indicate that the naturally-occurring arsenic concentrations in HNWR-1 water were 14-16 µg/L, greater than the federal and California MCL of 10 µg/L arsenic. Tables 1A and 1B summarize available analytical results for HNWR-1 (all tables and figures are presented at the end of this TM). As previously mentioned, the treatment goals for the FWPTS are to remove arsenic to concentrations less than 10 µg/L.

The total freshwater supply flow rates are based on the sum of the modeled freshwater flows into the Freshwater and Inner Recirculation Loop injection wells. The FWPTS will be designed to treat freshwater for remedy injection only. Exhibit 1 shows the FWPTS design flow rates.

EXHIBIT 1
Design Flow Rates
Addendum to Freshwater Pre-injection Treatment System Design Basis Memorandum
PG&E Topock Compressor Station, Needles, California

Element	Unit	Minimum Flow	Nominal Flow	Maximum Flow
Freshwater Pre-Injection Treatment System (FWPTS)	gpm	150	450	900

3.0 Evaluation and Selection of Treatment Technologies

For this conceptual design basis, PG&E has identified and evaluated proven treatment technologies for arsenic that are United States Environmental Protection Agency (USEPA) Best Available Technologies (USEPA 2001) and have been successfully used by municipalities and industry. Unproven technologies or technologies that have not been used in full-scale applications were not considered.

The initial list included nine technologies: anion exchange, activated alumina (AA) adsorbents, reverse osmosis (RO), electrodialysis reversal (EDR), lime softening, distillation, iron-based adsorbents, titanium-based adsorbents, and coagulation/filtration (see Exhibit 2). These technologies were evaluated and screened in a two-step process: (1) the initial screening was based on the experience of the engineering team with the individual technology, and (2) the second-level screening was based on a set of criteria - namely treatment effectiveness, reliability and flexibility[1], operational complexity, waste generation, footprint, and cost effectiveness. After completion of the technology screening and evaluation process, the AA technology with disposable and regenerable (AA) adsorptive media, coagulation filtration, and iron-based adsorbent granular ferric hydroxide (GFH) were selected for bench-scale testing. For more details of this screening and a description of the evaluation processes, see Attachment A.

EXHIBIT 2
Technologies Considered for Arsenic Removal
Addendum to Freshwater Pre-injection Treatment System Design Basis Memorandum
PG&E Topock Compressor Station, Needles, California

Technology	Evaluation Status
Anion exchange	Screened out, significant waste generation.
AA	Selected for bench-testing
Titanium-based adsorbents	Screened out, similar as other adsorbents considered, with less experience.
Reverse osmosis (RO)	Screened out, significant waste generation.
Electrodialysis reversal (EDR)	Screened out, significant waste generation.
Lime softening	Screened out, significant waste generation.
Distillation	Screened out, significant energy use and capital cost.
Coagulation filtration	Selected for bench-testing
Iron-based adsorbents	Selected for bench-testing

[1] Flexibility is defined as the ability of a system to respond to potential internal or external changes affecting its performance, in a timely and cost-effective manner. Also includes aspects such as handling changes in influent water quality and flowrates.

4.0 Summary of Bench-scale Testing Results

The objectives of bench-scale testing were to: (1) verify the effectiveness of each adsorptive media in removing arsenic from HNWR-1 water to the treatment goals, (2) understand the time to break through (critical for equipment sizing and waste management) for AA and GFH, (3) understand effectiveness of coagulation with a jar test, and (4) understand waste generation amounts. This section summarizes the testing and results to date as it relates to arsenic treatment.

To accomplish the first two objectives, CH2M HILL's ASL employs a testing procedure for evaluating adsorptive media effectiveness in removing arsenic in a small-diameter laboratory column analogous to the rapid small-scale column test method developed for assessing granular-activated carbon in a continuous flow system. This method significantly reduces the amount of time and water required for testing compared to pilot-scale and full-scale systems (USEPA 1996). A jar test was performed to evaluate the effectiveness of ferric chloride as coagulant.

A groundwater sample was continuously pumped, sampled, and collected in three 55-gallon drums from HNWR-1 well in early January 2013 and was shipped to ASL for bench-scale testing. The groundwater sample was processed continuously through the column, and the treated water was sampled and analyzed for arsenic until breakthrough (defined as at least 70 percent of the average influent concentration). After the first breakthrough, the media was regenerated, and the test was repeated. Two treatment cycles (termed Service Cycle 1 and Service Cycle 2) were conducted for regenerable AA (due to fluoride breakthrough caused by the greater affinity of fluoride versus arsenic to AA). Because of time constraints, not all media samples were able to be tested until arsenic breakthrough. In total, 133 liters of HNWR-1 well water were processed using disposable AA and 204 liters using GFH. These samples were tested for as long as time permitted in the laboratory. The rapid small-scale column test results provide information on adsorption capacity (extent of adsorption) and the rate of adsorption (adsorption kinetics), which are the two dominant factors affecting breakthrough in the media columns.

The rapid small-scale column test for arsenic removal was performed using the following media

- Regenerable AA (BASF AA-400G)
- Disposable AA (BASF AA-FS50)
- Alum-impregnated AA (AIAA)
- GFH

Prior to passing the water over the media, the groundwater was pretreated as follows: the pH was adjusted to 6.5 with hydrochloric acid and the water was injected with chlorine to maintain a residual concentration of 1 mg/L for 60 seconds (this is to oxidize any arsenite present in the water to arsenate), and was followed by inline filtration.

Column Testing Treatment Effectiveness and Time to Breakthrough

Figure 1 shows concentrations of arsenic in treated water versus the number of bed-volumes of groundwater passed through (one bed-volume is equivalent to the amount of adsorptive media in the column). During the first service cycle, the regenerable AA performs well, but in the second service cycle the effluent concentration begins to increase more rapidly indicating after the initial service cycle the media loses capacity to adsorb arsenic. Due to this fact and the difficulty in regenerating AA media which requires using strong chemicals like caustic and sulfuric acid increasing safety concerns, cost, and associated wastewater management[2], this method is eliminated from further analysis. The AIAA performed somewhat better than the regenerable AA, but not as well as the disposable AA media. The poorer performance and the additional effort to impregnate the alum onto the AA, eliminates this media from further evaluation. The disposable media performed well to more than 44,000 bed volumes, although the arsenic effluent concentration appears to have increased more than the effluent from the GFH media column.

To ascertain the relative performance of the two media, another figure was prepared (Figure 2), which shows the measured effluent concentration as a function of the amount of arsenic adsorbed on the treatment media. The amount of arsenic absorbed was calculated by multiplying the measured concentration in effluent samples by the volume of water passing through during the sampling interval and dividing by the mass of media in the column.

[2] The estimated wastewater volume ranged from 3.3 to 11 million gallons per year (CH2M HILL 2013).

The effluent concentration in the disposable AA, begins to rise rapidly when the adsorption reaches 0.4 µg/mg media where as in the GFH varies between 0.15 and 0.35 µg/mg media until the test was stopped. These results more clearly indicate GFH will perform better.

Jar Testing Results

Jar testing was performed to test arsenic removal by coagulation with ferric chloride. Water samples were pre-oxidized with free chlorine dosed to provide approximately 1 mg/L free chlorine residual for 60 seconds prior to ferric chloride addition and mixing. Ferric chloride was added to reach doses 5, 10, 15, and 20 mg/L. The mixers were run at 70 revolutions per minute (rpm) for 30 seconds followed by 25 rpm for 20 minutes. The samples were then filtered through a 0.45 micron filter and the filtered water tested for arsenic and pH.

Figure 3 shows the arsenic concentration versus ferric chloride dose applied during testing. Jar testing demonstrated that arsenic could effectively be removed to <10 µg/L with ferric chloride dosed to 5 mg/L.

Process Selection

As shown above, the GFH was effective at removing arsenic to below the treatment goals (the federal and California MCL of 10 µg/L). The effluent remained less than 1 µg/L of arsenic for over 70,000 bed-volumes. The GFH media performed better than the disposable AA offering longer running periods between media change-outs. Coagulation and filtration although effective creates a solid waste stream 5 times greater than GFH that must be transported and disposed of off-site and is more difficult to operate. Based on these reasons, GFH was selected for the FWPTS design.

Section 5 discusses the treatment and backwash process in more details and provides a summary of the sustainability factors.

5.0 Freshwater Treatment Process and System Description

As previously mentioned, GFH was selected as the treatment technology to be carried forward into the design of the FWPTS. GFH is a granular, ferric-based, non-regenerative media that adsorbs arsenic and other heavy metal ions from solution. The USEPA has identified GFH as an effective media to remove arsenic (USEPA 2003). This section describes the design philosophy, the treatment process, and the system configuration envisioned at this stage. This section also discusses the uncertainties with the ongoing design and the work that is currently underway or being planned to address these uncertainties.

5.1 Treatment System Description

Groundwater will be pumped and conveyed from the future water supply well in Arizona to the remedy freshwater storage tank. Water will be pumped from this tank and will be injected with hypochlorite for arsenic oxidation and with acid to reduce pH to 6.5; both hypochlorite and lower pH improve arsenic removal in the media vessels. After chemical injection, water will be passed through cartridge filters to remove solids that would otherwise clog the media, reducing performance and runtime. With the solids removed, the water will be divided into two or three streams (nominal or maximum flow) and each will be processed through a single treatment media vessel (configured in parallel) in a downward flow direction. Automatic valves will divert the flow to the proper vessels and will control the flow rate into each in service vessel. During nominal flow, the third and treatment media vessel will be in standby mode. During maximum flow, three treatment media vessels will be operating.

PG&E evaluated dechlorination alternatives to remove residual chlorine from the treated freshwater. The reason for this step is to prevent the dechlorination chemicals in the freshwater plume from adversely effecting microorganisms in the remediation zones. Dechlorination is often accomplished by addition of commonly used chemicals such as ascorbic acid, calcium thiosulfate, and hydrogen peroxide. The evaluation included cost-effectiveness and safety issues related with handling and storage, and the results showed calcium thiosulfate was the best. The equipment needed include chemical storage tanks or totes, metering pumps, and an inline static mixer. Due to climate condition at Topock, the equipment would be housed in an air-conditioned storage building.

5.2 Media Backwash & Replacement Process

The amount of wastewater generated is primarily a function of backwash frequency. Backwashing prevents over compaction of the media bed enabling good flow conditions. The media bed should be backwashed once a month for proper media maintenance. Backwashing occurs in an upflow mode, the reverse of normal forward down-flow operation. Once the backwash process is complete, normal forward down-flow operation may resume. Each media vessel backwash process is expected take ten minutes.

At some point during treatment operations, the media will lose its adsorptive capacity and will need to be replaced. Based on bench scale testing, this point is anticipated to be after more than 70,000 bed-volumes or about 8 months at maximum flow rates. The actual replacement frequency will be determined during full-scale operation. For the purpose of the conceptual design, it is assumed that the media will be replaced once a year. Spent media will be removed from each vessel and sent to a landfill. Prior experience operating GFH treatment process shows the spent media is not hazardous (Ela 2006). Waste characterization testing will be performed in accordance with state and federal requirements and facility waste acceptance procedures. Virgin media will be placed in the media vessel and normal forward down-flow operation may resume.

Wastewater & Solid Waste Generation

The volume of wastewater needing to be managed is estimated based on the following assumptions:

- Backwash rate is 15 gpm/sq. ft. and vessel cross section area is 50 sq. ft.
- Backwashing time is 10 minutes resulting in 7,550 gallons per backwash
- Four vessels backwashed monthly at 900 gpm and two vessels backwashed monthly at 450 gpm
- 95 percent of the backwash water is recycled to the beginning of the process

At 450 gpm – 7,550 gallons/backwash x 2 vessels per month x 12 months per year x 5% = 9,000 gallons per year

For 900 gpm – 7,550 gallons/backwash x 4 vessels per month x 12 months per year x 5% = 18,000 gallons per year

The remaining (5 percent of the) backwash water can be discharged to the TCS evaporation ponds or disposed offsite at permitted facilities. There is no need to treat or neutralize the pH of the discharged backwash water as it will be within acceptable ranges. Treated water is used for backwashing and no arsenic desorbs from the media during the backwashing process. Discharged backwash water will have more solids compared to the treated water but it will be able to be pumped to the TCS evaporation ponds or disposed offsite without treatment.

Periodic disposal of the spent GFH media would be required also as a solid waste stream. Based on the bench testing, this would be no more frequently than every 8 months, but is expected to be less frequent. For the purposes of this conceptual design, it is assumed that the media will require annual replacement. The mass of solid waste to be managed

- The media has a specific gravity of 1.1 with water density of 62.4 pounds per cubic foot
- Each vessel has 200 cubic feet of media
- Four vessels need replacement at a rate 900 gpm and 2 vessels at a rate of 450 gpm

At 450 gpm – 200 cubic feet/vessel x 2 vessels per year x 1.1 x 62.4 pounds per cubic foot / 2,000 tons/pound = 13.7 tons per year

At 900 gpm – 200 cubic feet/vessel x 4 vessels per year x 1.1 x 62.4 pounds per cubic foot / 2,000 tons/pound = 27.5 tons per year

5.3 Chemical and Media Use

Chemicals will be used in the treatment system. Chlorine in the form of calcium hypochlorite tablets is used to oxidize arsenite to arsenate. Arsenate is more readily removed by the treatment process. Acid is used in pretreatment to improve adsorption by lowering the pH to about 6.5. The estimated chemical use is shown in Exhibit 3.

EXHIBIT 3
Annual Chemical Usage Rates
Addendum to Freshwater Pre-injection Treatment System Design Basis Memorandum
PG&E Topock Compressor Station, Needles, California

Flow Case	Flowrate, gpm	Hypochlorite, pounds/year	93% Sulfuric Acid, gallons/year	Calcium Thiosulfate
Nominal	450	3,500	5,150	2,550
Maximum	900	7,000	10,300	1,275

5.4 Sustainability Summary

For each of the treatment plant operating scenarios (450 and 900 gpm), sustainability parameters such as waste generation, chemical usage, energy use, and greenhouse gas emissions were estimated for the FWPTS as shown on Exhibit 4.

EXHIBIT 4
Sustainability Summary [a]
Addendum to Freshwater Pre-injection Treatment System Design Basis Memorandum
PG&E Topock Compressor Station, Needles, California

	Operations								Construction	
Treatment Case	Chemical Truck Trips	Solid Waste Truck Trips	Electricity, kw-hr/yr	Wastewater Generation, MG/yr	Solid Waste Generated, tons/ year[b]	Chemical Use, gal/yr	Total Miles/ year	Emissions, CO2 eq, Tons/year[c]	CO2 eq, Tons [d]	Footprint, sf [e]
450 gpm	20	2	280,000	Minimal	17	21,300	7,000	180	210	2,400
900 gpm	39	~3	320,000	Minimal	33	42,500	13,000	200	250	3,900

Notes:
Units: kw-hr/year = kilowatt-hours per year; MG/yr = million gallons per year; gal = gallons; sf = square feet; gpm=gal per minute; CO2 eq – carbon dioxide equivalent
[a] Previously submitted on March 29, 2013. Additional effects for using a dechlorination agent if required will be added to this table in the 90% design submittal.
[b] Solid waste includes spent filter cartridges (500 to 1,000 per year)
[c] Operational emissions include vehicle emission and electricity generation
[d] Construction includes site work, material delivery, and workers travel
[e] Footprint based on foundations for building, process tanks, and chemical storage

5.5 Controls Philosophy

The system will be automated to reduce the need for continuous operator oversight. Electronic notifications will be sent automatically to on-site operators that notify them of system alarms, shutdown, or other issues. System automation will be controlled using a programmable logic controller that will communicate with the groundwater remedy supervisory control and data acquisition system. Pneumatic valves will be automated to control flow. Online pH, turbidity, and conductivity sensors will be incorporated to enable remote process monitoring and control. Arsenic cannot be monitored using an online analyzer. Grab samples will be collected periodically and analyzed using a bench top colorimetric instrument in the sample room (located in the Remedy Produced Water Conditioning Building) to monitor arsenic levels.

5.6 Other Related Systems and Infrastructure

Electricity will be provided from the Compressor Station. The new FWPTS location will have a heating, ventilation, and air conditioning (HVAC) system for only critical equipment such as electrical and controls equipment.

5.7 Design Philosophy/Uncertainties in Design

As previously mentioned, the FWPTS will be designed to achieve a safe, efficient, and sustainable operation within the compressor station over the anticipated decades-long life of the remedy. Most of the uncertainty in the design is related to the bed life and adsorptive capacity of the media. Based on bench testing, it is anticipated that the media will not need to be replaced before 70,000 bed volumes are processed– or every 8 months. The actual adsorptive capacity will need to be determined during full-scale operation and the result will greatly influence the amount of wastewater and solid waste generated by the process.

6.0 Design Information

Process calculations used to develop the design criteria were prepared using the conservative assumption that the treatment vessels each needed to be backwashed once a month and media replaced annually. Conceptual design information is presented in Tables 2, 3, and 4 and on Figures 4, 5, and 6.

TABLE 2

Design Criteria for Arsenic Treatment System

Addendum to Freshwater Pre-injection Treatment System Design Basis Memorandum
PG&E Topock Compressor Station, Needles, California

Subject	Criteria	Comments/Reason
OPERATIONAL CRITERIA		
Maximum Groundwater Injection Flow Capacity	900 gpm	
Minimum Groundwater Injection Flow Capacity	150 gpm	
Average Groundwater Injection Flow Capacity	450 gpm	
SITE CIVIL		
Location	Designated freshwater treatment at PG&E Topock Compressor Station near Needles, California. Next to the Remedy Produced Water Conditioning Building, within the footprint of the planned Decontamination Pad	
Building Finish Floor Elevation	Finished first floor, Elevation 626 feet (NGVD88).	
Grading	Longitudinal Slopes: Minimum 1% away from structures (2% desirable).	
Vehicle Access	WB 50 (turning radius for semi-truck and trailer with 50-foot wheel base). HS 20 (wheel loading on access roadways and parking areas). 50-foot minimum turning radius. Designated site accommodates truck circulation. Roads will be constructed at new facility for maintenance activities.	Required for delivery of chemicals, pumps, motors, and fire vehicles.
Site Constraints	Proposed facility located within the boundary of the compressor station. Access to all critical compressor station facilities must be maintained.	No modifications to the perimeter site fence or entrance gate will be made.
Parking	No parking will be required for new facility.	
Pedestrian Traffic	Limited to paved roadways, sidewalks are not located between existing facilities.	
PROCESS EQUIPMENT, MOTORS, VALVES, AND ANCILLARIES		
Treatment Process	Pre-oxidation, influent pH adjustment, followed by ligand exchange with granular ferric hydroxide for arsenic removal. Periodic backwash of media with treated water and annual media replacement. Treated water will be dechlorinated to limit adverse effects on microorganisms and remedy performance (see Dechlorination System below).	Design criteria listed below is what is expected from planned pre-purchase bid, but not a guarantee of what equipment will be selected.

TABLE 2

Design Criteria for Arsenic Treatment System

Addendum to Freshwater Pre-injection Treatment System Design Basis Memorandum
PG&E Topock Compressor Station, Needles, California

Subject	Criteria	Comments/Reason
Granular Ferric Hydroxide (GFH) Treatment		
Treatment Objective	Arsenic removal	
Number of Vessels	Three when operating a maximum flow: Three online. Two online when operating at nominal flow;	Three vessels were included in the 90% design instead of four following a value engineering evaluation. Three vessels on-line will meet treatment requirements and have a very small effect on performance because the total downtime during backwashing (i.e., vessel is off-line) is 30 minutes per month (<0.1% of time).
Residence Time	5 minutes empty bed contact time	USEPA guidance.
Vessel Height	10.5 feet overall	
Vessel Diameter	8 feet	4 to 8 gpm/ft^2 hydraulic loading.
Materials of Construction	Low-carbon steel with epoxy lining that is NSF 61 listed.	
Media	Granular ferric hydroxide	Siemens, Severn Trent, or equal
Performance Limits		
Effluent Arsenic Concentration	< 10 µg/L	
Wastewater Volume	9,000 – 18,000 gal/year	
Chlorine Feed System		
Chemical Feed System	One calcium hypochlorite tablet feeder system—HDXLPE (with oxidation resistant liner) mix tank, feed pump, tablet hopper, controller and panel with disconnect. Sized for 0.2 to 2 lbs/hour of chlorine. Three days' minimum tablet capacity.	Feed system located in a containment area.
Safety Equipment	One eyewash and shower unit	Located in chemical storage area.
Coatings/Finishes	Chemical resistant coatings in chemical areas	
Controls	Chemical feed pump speed control	
Sulfuric Acid Feed System		
Chemical Feed System	One 1,000-gallon carbon steel with baked phenolic lining. Desiccant drier installed on vent. Sulfuric acid tank with tank pad. One chemical feed skid with two controllable chemical feed pumps (up to 2 gal/hour)	Tank will be located in a containment area. Monthly fill frequency is the design basis. Solution concentration will be 93%.
Safety Equipment	One eyewash and shower unit	Located in chemical storage area.
Coatings/Finishes	Chemical resistant coatings in chemical areas	
Controls	Chemical feed pump speed control	
Backwash Tank and Treated Water Tank		
Material	Fiberglass Reinforced Plastic (FRP)	
Number	Two	

TABLE 2

Design Criteria for Arsenic Treatment System

Addendum to Freshwater Pre-injection Treatment System Design Basis Memorandum
PG&E Topock Compressor Station, Needles, California

Subject	Criteria	Comments/Reason
Capacity	10,000-gallons tanks	Backwash is anticipated to be just over 7,000 gallons per vessel – 10 minutes of backwashing at 15 gpm/ft^2. Backwash tank will have floating decanter and cone bottom to aid in solids recovery and improve backwash recycle rate. Treated water tank will be flat-bottomed. Both tanks will be equipped with ladders and top access platforms with safety cages and railings.
Dechlorination System		Chemical selected for use in dechlorination is calcium thiosulfate.
Chemical Feed System	Drums or chemical tote compatible with calcium thiosulfate. One chemical feed skid with two controllable chemical feed pumps	Container will be located in a containment area. Monthly fill frequency is the design basis, It is assumed there is sufficient space for this equipment.
Safety Equipment	One eyewash and shower unit	Located in chemical storage area.
Coatings/Finishes	Chemical resistant coatings in chemical areas	
Controls	Chemical feed pump speed control Inline static mixer	
Flow Meters		
Type	Magnetic	
Number	Seven	
Flow Control Strategy	FWPTS will receive raw water from the primary source well (HNWR-1A) into a new freshwater storage tank (10,000 gallons). The secondary sources (HNWR-1 and Site B) may be connected to the pipeline in the future. PG&E is considering augmenting the supply with a gravity flow line from the existing TCS storage tanks only when required.) A booster pump with variable frequency drive will vary the flow through the treatment plant to maintain set point water levels in the treated water tank and prevent pump operating when the remedy freshwater storage tank water levels are below the setpoint. Media vessel inlet control valves equalize flows through each vessel based on flowmeters located downstream of each media vessel.	
Pressure Transmitters	Furnished before/after media vessels.	
Static Mixer		
Number	Two (at the inlet and outlet)	
Diameter	10-inch	
Type	Wafer style with integral injection ports	

TABLE 2

Design Criteria for Arsenic Treatment System

Addendum to Freshwater Pre-injection Treatment System Design Basis Memorandum
PG&E Topock Compressor Station, Needles, California

Subject	Criteria	Comments/Reason
Piping Materials		
Process	HDPE SDR 11 or CPVC Schedule 80, per ASTM D1784, ASTM D1785, and NSF/ANSI 14 and NSF 61 listed	
Treatment Media Vessel Manifold	HDPE SDR 11 or CPVC Schedule 80, per ASTM D178, ASTM D1785, NSF/ANSI 14 and NSF-61 listed	
Potable Water	Buried: Copper, Type K, per ASTM B88 Exposed: Copper, Type L, per ASTM B88 or CPVC Sch. 80	
Process Piping Installation	Major process piping headers will be installed in pipe trenches inside the treatment building and buried outside the building. Media vessel piping will be aboveground. Actuated valves will be installed above grade whenever possible.	
Remedy freshwater storage tank Interface	Inlet from Remedy freshwater storage tank	
YARD PIPING		
Design Criteria	Appendix C, Basis of Design Report (CH2M HILL 2014)	
CORROSION CONTROL

Cooling Load Basis	Building envelope heat gain and internal heat gains from equipment.	
System Type		
Process Building	A free standing electrical and controls equipment panel will be installed. The panel will have dedicated cooling system.	
PLUMBING		
Lavatory/Toilet Room	No facilities provided.	
Potable Water	Emergency shower/eye wash stations.	Per 2010 California Plumbing Code, and ANSI Z358.1.

TABLE 2

Design Criteria for Arsenic Treatment System

Addendum to Freshwater Pre-injection Treatment System Design Basis Memorandum
PG&E Topock Compressor Station, Needles, California

Subject	Criteria	Comments/Reason
Non-potable Water	The non-potable water supply will have a reduced pressure backflow preventer. Non-potable water will be supplied for wash down water. Wash down hose valves, hoses and hose racks will be furnished in the area as required.	Per 2010 California Plumbing Code.
ELECTRICAL		
Electrical Load	The electrical load will consist of process pumps, motor operated valves, filter system, control panel and instrumentation, building HVAC, convenience receptacles and interior and exterior lighting. Power distribution will be sized in accordance with NFPA 70 (National Electric Code) to operate process and facility loads. Short-circuit current interrupting capacity of power distribution equipment will be coordinated with existing power distribution system.	.
Service Voltage	480V, 3-phase, 3-wire power will be supplied from XFMR 099	
Utilization Voltage	Appendix C, Basis of Design Report (CH2M HILL 2014)	
Redundancy Requirements	Power distribution system redundancy will be limited to equipment supporting the operation of back-up process and facility equipment (i.e. motor control combination starters, and breakers,). Power distribution system for FWPTS will incorporate spare breakers and fuses. Supporting quick replacement of failed components. Backup power when needed by portable diesel generator located near Remedy Produced Conditioning Building.	.
Manufacturers of Electrical Equipment, Grounding, Lightning Protection, Illumination, Emergency Lights, Stand-by/Backup Power, Raceways, and Duct Banks	Appendix C, Basis of Design Report (CH2M HILL 2014)	
SECURITY		
Security	None	All security covered through TCS main facility
CONTROL AND TELEMETRY		
Control and Telemetry Design Criteria	The treatment vessels will be a packaged system with the equipment manufacturer providing a fully configured programmable logic controller based system control panel with panel-mounted operator interface terminal. The control panel will be specified with an uninterruptible power supply to provide true online conditioned power sized to operate the connected load for 30 minutes.	

TABLE 2

Design Criteria for Arsenic Treatment System

Addendum to Freshwater Pre-injection Treatment System Design Basis Memorandum
PG&E Topock Compressor Station, Needles, California

Subject	Criteria	Comments/Reason
Communications, Other Networks, Supervisory Control and Data Acquisition, Instrumentation	Appendix C, Basis of Design Report (CH2M HILL 2014)	
Environmental Requirements	Equipment and instrumentation will be suitable for the following conditions: Air-conditioned Spaces: 10°C to 35°C and a relative humidity of 10 to 80 percent. Non-air-conditioned Spaces: 0°C to 50°C and a relative humidity of 10 to 95 percent. Outdoors: 0°C to 60°C and a relative humidity of 5 to 100 percent.	Environmental controls, such as heaters, fans, and air conditioning will be provided to maintain equipment within the operating conditions recommended by the manufacturer.
Standards/References	Appendix C, Basis of Design Report (CH2M HILL 2014)	

TABLE 3
Major Equipment List
Addendum to Freshwater Pre-injection Treatment System Design Basis Memorandum
PG&E Topock Compressor Station, Needles, California

Quantity	Name	Description
3	Treatment Media Vessels	8-feet-diameter low-carbon steel with epoxy lining (4 - 8 gpm/ft^2 hydraulic loading rate)
1	Hypochlorite Feeder	Calcium hypochlorite tablet feeder: HDXLPE (with oxidation-resistant liner) mix tank, feed pump, tablet hopper, controller, and panel with disconnect
1	Sulfuric Acid Tank	1,000-gallon, (93% sulfuric acid), desiccant drier installed on vent. Baked phenolic lining on steel.
1	Acid Feed System	Pre-engineered skid with two chemical metering pumps for 93% sulfuric acid (0.5 to 2 gph)
1	Dechlorination System	Pre-engineered chemical feed skid to pump calcium thiosulfate, storage tote(s) or tanks, and static mixer. Air-conditioned chemical storage shed will be provided to maintain chemical quality.
2	Pre-and post-treatment Wafer-Style Static Mixers	With integral injection ports
2	Booster Pumps	Centrifugal pump with variable frequency drive
2	Filters skids with replaceable elements	Package unit with differential pressure indication and alarm and flow control valves to divert water to the online filter. Cartridge type
2	Backwash Recycle Pumps	Multistage centrifugal pump
2	Backwash Pumps	Centrifugal pump 755 gpm (15 gpm/ft^2 hydraulic loading rate)

Attachment A
Arsenic and Fluoride Treatment Technology Screening

ATTACHMENT A

Arsenic and Fluoride Treatment Technology Screening

As part of the pre-conceptual design work, several treatment technologies were identified and screened to help select an effective and efficient treatment process for two removal processes -- arsenic/fluoride removal and arsenic only removal. After technology identification, the list was screened qualitatively with a more detailed screening was completed on a short list of five technologies. Bench-scale testing was then performed to select the technology to carry forward into design.

A.1 Initial Screening

The United States Environmental Protection Agency, water and wastewater utilities, industrial concerns, research universities and centers, and industry groups have published numerous case studies and reports on testing and performance of these technologies in treating arsenic and fluoride in water (American Water Works Association, 1999; Odell, 2010). The initial list of technologies evaluated for the Topock freshwater pre-injection treatment system was developed from those technologies that have been successfully used by municipalities and industry. Unproven technologies or technologies that have not been used in full-scale applications were not considered in the screening. The initial list included anion exchange, activated alumina (AA), reverse osmosis (RO), electrodialysis reversal (EDR), lime softening, distillation, iron-based adsorbents, titanium-based adsorbents, and coagulation/filtration. The status of selection is summarized in Table A-1.

TABLE A-1
Technologies Considered for Arsenic and Fluoride Removal
Addendum to Freshwater Pre-injection Treatment System Design Basis Memorandum
PG&E Topock Compressor Station, Needles, California

Technology	Status
Anion exchange	Screened out, significant waste generation.
Activated Alumina (AA)	Selected for bench-testing. Primary treatment option is regenerable AA if arsenic and fluoride treatment required.
Titanium-based adsorbents	Screened out, similar as other adsorbents considered, with less experience.
Reverse Osmosis (RO)	Screened out, significant waste generation.
Electrodialysis Reversal (EDR)	Screened out, significant waste generation.
Lime Softening	Screened out, significant waste generation.
Distillation	Screened out, significant energy use and capital cost.
Coagulation Filtration	Screened out, this process does not treat fluoride. If arsenic-only treatment is required, this technology would be screened out due to more residuals are generated, additional chemicals are used, and the process is more complex than iron-based adsorbents. However, it will be retained for bench-scale testing for data collection due to the quick and simple test.
Iron-based Adsorbents	Screened out, this process does not treat fluoride. If arsenic-only treatment required, this process may be used.

A brief process description is provided below.

Anion Exchange. Anions such as fluoride, nitrate, arsenate, selenate, and chromate can be removed from water by using ion exchange with resin. This physical-chemical process involves an easily displaceable ion on the solid phase, exchanging with an unwanted ion in the water that adsorbs to the solid phase. To accomplish the exchange reaction, a packed bed of ion-exchange resin beads is used. Source water is continually passed through the bed in a downflow or upflow mode until the adsorbent is exhausted, as evidenced by the appearance (breakthrough) of the unwanted contaminant at an unacceptable concentration in the effluent.

The most useful ion-exchange reactions are reversible. In the simplest cases, the exhausted bed is regenerated using an excess of the displaceable ion in the form of salt brine. Ideally, no permanent media structural change occurs during the exhaustion/regeneration cycle. This is a proven technology, is widely used, and is easy to automate, but it generates considerable wastewater.

Activated Alumina*.* AA is a semi-crystalline porous inorganic adsorbent, is a proven technology for fluoride removal, and effectively removes arsenic. The removal mechanism, which is one of exchange of contaminant anions for surface hydroxides on the alumina, is generally called adsorption, although ligand exchange is a more appropriate term for the highly specific surface reactions involved. Packed beds of AA are used in water treatment plants in a similar manner to anion exchange. Regeneration is accomplished using a basic solution like sodium hydroxide (caustic). The adsorbent media can be purchased in a disposable form as well. In this case, the spent media is disposed in an offsite facility. This is a proven technology, is widely used, is easy to automate, but it generates considerable wastewater.

Titanium-based adsorbents*.* These are porous adsorbents made with titanium that work similarly to AA in that surface hydroxides exchange with fluoride in the water stream. Similarly, caustic is used to regenerate the adsorbent in the packed beds. This is a newer process with fewer systems in service.

Reverse Osmosis. RO is a membrane water treatment system in which water is pressurized to more than 100 pounds per square inch and is directed through small pores in a synthetic membrane. Treated water is produced through the other side of the small pores while larger particulates are retained on the inlet side of the membrane. RO is effective in removing uranium, radium, arsenic, fluoride, nitrates, microbial contaminants, and many chemicals. Because of the high pressure required for the process, RO systems typically are energy-intensive and have high initial costs. Furthermore, these systems can require more operator attention and can require membrane integrity testing. RO systems also risk fouling and scaling from hard water, colloids, and bacteria. The fouling and scaling increase the pressure drop and result in a shorter lifetime for the membrane or frequent chemical cleaning. In addition, this process generates considerable volumes of wastewater.

Electrodialysis Reversal. EDR is a membrane water treatment process that relies on polarizing electrodes to remove contaminants. The ions in the water are attracted to the membrane by a cathode or anode. Once attracted to the membrane, the ion is transported electrically through the membrane. EDR systems reverse the polarity of the electrodes every 15 to 20 minutes. This process releases accumulated ions and has the following advantages:

- Breaks up scale and reduces the potential for scaling.
- Reduces microbiological growth on the membrane.
- Reduces membrane cleaning frequency.

EDR systems operate at higher pressures than most water treatment systems but not as high as RO systems. They are maintenance intensive and generate considerable volumes of wastewater.

Lime Softening. Hardness in water is characterized by elevated levels of magnesium and calcium. Lime softening removes the hardness by mixing lime (slaked or hydrated) during the treatment process. The lime addition increases the pH of the water and causes the magnesium and calcium to precipitate out. Flocculation and sedimentation units are employed to provide a sufficient time and space to accumulate solids. Magnesium requires a higher pH than calcium to cause precipitation and results in water with a pH as high as 11. Carbon dioxide is used commonly to reduce the pH back to desired levels. This process, although used often, requires

careful chemical dosing and process monitoring, requires large amounts of chemicals, and generates large amounts of waste sludge.

Distillation. To distill water, water is heated until boiling and vaporized. The resulting steam is collected and condensed in a clean storage tank. Distillation is effective in removing metals, hardness, and particulates because they do not vaporize with the water. The boiling process also kills bacteria and some viruses. Distillation is ineffective in removing contaminants with a lower boiling point than water, such as benzene. These contaminants must be removed before condensation or recontamination will occur. This process is straightforward to operate but uses high amounts of energy and requires costly metal alloys for construction.

Coagulation Filtration. Coagulation is a process in which smaller particles in suspension attach to one another through electrostatic forces. As the particles attach to one another, larger particles start to form. Aluminum and ferric salts are the most commonly used compounds to enhance coagulation because aluminum or iron hydroxide is formed. Once finished with the coagulation process, the water is filtered through a media filter or microfilter to remove the aggregated particles. Coagulation filtration has been found very effective in removing arsenic from water. While often some form of pretreatment is needed (usually chlorine oxidation), coagulation filtration systems can achieve over a 90 percent reduction in arsenic. However, this process does not treat fluoride. The process is relatively easy to operate.

Iron-based Adsorbents. Contaminated water is passed through a pressure vessel that contains iron based adsorbents that remove arsenic. Granular ferric hydroxide is a common example that is in an amorphous crystalline form. Iron-based adsorbents have been shown effective in removing arsenic (not fluoride) at pH levels normally found in drinking water; however, best performance happens at lower pH levels. Lower pH levels may result in the need for more operator attention and the possibility of handling hazardous chemicals. Once the media has been lost its adsorbent capacity, the spent media is replaced.

A.1.1 Initial Screening Results

As a result of the screening, four technologies were retained for further evaluation:

- AA adsorption – disposal media and regenerable media
- Iron-based adsorbents
- Coagulation/filtration

The following technologies were rejected based on the reasons listed below.

- **Anion exchange, EDR, and RO:** processes generate large residual wastewater streams that must be disposed of.
- **Lime softening:** generates large volume of waste sludge that is difficult and costly to dispose of.
- **Titanium-based adsorbents:** effective at very low pH or with expensive rare earth metals and has the fewest number of operating systems.
- **Distillation:** high cost for energy use.

A.2 Second-level Screening

The two remaining technologies were screened at a second level with AA divided into regenerable and disposable forms. The screening criteria were as follows:

1. Treatment Effectiveness
   - Ability to achieve treatment goals
2. Reliability and Flexibility
   - Ability to allow variation in influent water
   - Expandability

3. Operational Complexity
   - Ease of operation
   - Safety
4. Waste Generation
   - Quantity and quality
5. Footprint
6. Cost Effectiveness

As a result of the screening, anion exchange was not carried forward and was dropped from further consideration because of its lower effectiveness, greater operational complexity, the wastewater volumes generated, and its higher operating cost. The four processes— regenerable AA and disposable AA, iron-based adsorbents, and coagulation/filtration —were advanced to bench-scale testing.

A.3 Bench-scale Testing

As described in the body of the Design Basis Technical Memorandum, bench-scale testing was performed after the technology screening. Testing showed that regenerable AA and iron-based adsorbent were the technologies that best met design needs if both arsenic and fluoride removal, or arsenic removal alone is required Disposable AA was eliminated from further evaluation.

This technical memorandum is required to communicate the findings of the Evaluation of Alternative Freshwater Sources for the groundwater remedy as directed with DTSC's September 4, 2013, letter, DOI's September 4, 2013, letter, and DTSC and DOI's joint email on November 6, 2013. Feedback received on this document will be considered for a subsequent draft, as necessary, which will be included as an appendix to the forthcoming Groundwater Remedy Pre-final (90%) Basis of Design document. This report is in compliance with the RFI/RI process.

Other Justification/s:

☐ Permit ☐ Other / Explain:

Brief Summary of attached document:

As an element of the final groundwater remedy design, freshwater sources, including groundwater supply wells and the Colorado River, have been considered for use during remedy operation. The average and maximum volume of freshwater required for remedy operation is estimated to be 450 and 900 gallons per minute (gpm), respectively, based on groundwater modeling. In the Basis of Design Report/Intermediate (60%) Design for the Final Groundwater Remedy, PG&E presented a plan to obtain freshwater from a well on the Havasu National Wildlife Refuge (HNWR)—well HNWR-1. This evaluation was conducted based on concern raised by DTSC in their August 8, 2012 letter regarding water quality from the proposed remedy freshwater source.

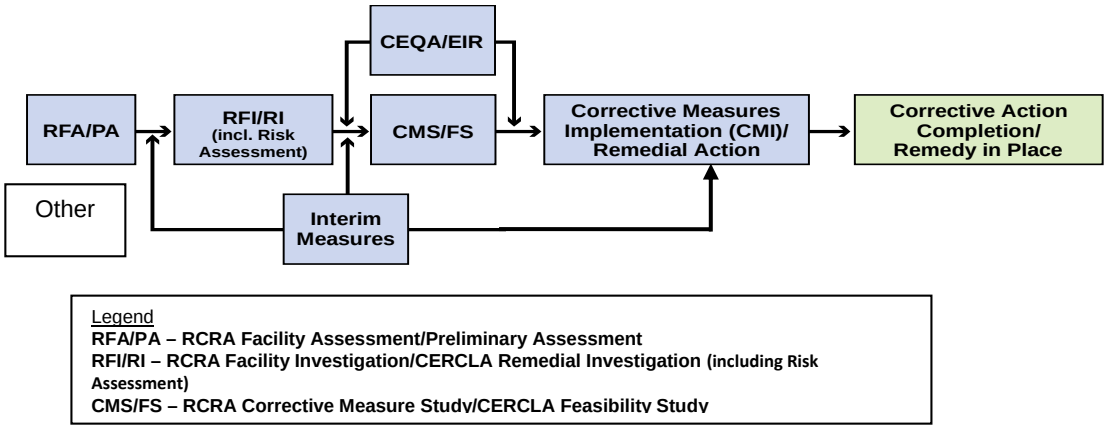
This technical memorandum summarizes the activities conducted and associated findings for the evaluation of alterative freshwater sources as defined in the Final Implementation Plan for Evaluation of Alternative Freshwater Sources in the Topock Remediation Project Areas, Pacific Gas and Electric Company, Topock Compressor Station, Needles, California (Work Plan).

Written by: Pacific Gas and Electric Company

Recommendations:

Provide input to the regulatory agencies.

How is this information related to the Final Remedy or Regulatory Requirements:



This technical memorandum communicates the conclusions and associated recommendations for the Evaluation of Alternate Freshwater Sources for the groundwater remedy.

Other requirements of this information?

None.

Summary of Findings Associated with the Evaluation of Alternative Freshwater Sources in the Topock Remediation Project Area, Pacific Gas and Electric Company, Topock Compressor Station, Needles, California

DOCUMENT ID:	PGE20140402A
PREPARED FOR:	Pacific Gas and Electric Company
PREPARED BY:	CH2M HILL
DATE:	April 2, 2014

Summary

This technical memorandum summarizes the activities conducted and associated findings for the evaluation of alterative freshwater sources as defined in the *Final Implementation Plan for Evaluation of Alternative Freshwater Sources in the Topock Remediation Project Areas, Pacific Gas and Electric Company, Topock Compressor Station, Needles, California* (Work Plan) (CH2M HILL, 2013b). The following primary activities were conducted at the two freshwater source evaluation locations (Site B and the area of the existing Havasu National Wildlife Refuge (HNWR) well, referred to herein as the HNWR-1 Site) (see Figure 1) during the implementation of the Work Plan, which was conducted in phases from October 2013 to February 2014:

- Installed exploratory boreholes at Site B and the HNWR-1 Site to a depth of 400 feet below ground surface (bgs) to facilitate collecting lithologic and zone-specific groundwater samples.
- Constructed a new well at Site B using the exploratory borehole as a pilot hole.
- Conducted an in-well video survey of the existing HNWR-1 well to confirm well construction details and evaluate the general well condition.
- Performed well and aquifer testing, including step-rate extraction tests and 72-hour constant rate extraction tests, at the existing HNWR-1 well and the new Site B well to evaluate well performance and estimate aquifer properties.
- Irrigated water pumped during Site B well development and all well testing activities at the HNWR future re-vegetation plot, as indicated in the Work Plan (CH2M HILL, 2013b).
- Conducted pre-construction surveys for biological, paleontological, and cultural resources (post-construction biological survey is pending).
- Conducted monitoring for biological, paleontological, and cultural resources during all fieldwork.

In addition to discussion during routine project meetings, three conference calls with the Technical Working Group (TWG) were held to provide updates on project activities and provide preliminary summaries of the data collected. These calls were held on November 4, 2013, January 29, 2014, and February 28, 2014. In addition to these calls, options for freshwater supply for the remedy and conceptual pipeline routing and infrastructure that would be associated with the freshwater supply well(s) were discussed during the March 19, 2014, TWG meeting.

Following is a summary of key findings from this evaluation:

- **Refined understanding of the unconsolidated aquifer in Arizona.** Data collected from the exploratory boreholes indicate that the unconsolidated aquifer at both locations is comprised largely of well-graded gravels with sand. Grab water quality samples at both locations indicate a stratified aquifer with higher

specific conductance (saltier) water occurring deeper in the borehole, and a more fresh (less salty) water occurring in the shallower intervals. The fresh (less salty) water at Site B is approximately 100 feet thicker than at the HNWR-1 Site. Both the Site B and HNWR-1 Site exploratory locations are located within the large fluvial plain of the pre-dam era Colorado River, and the detailed drilling logs describe these clean fluvial deposits at a greater frequency and thickness than the fluvial deposits on the California side of the River, which represents the thin western edge of the fluvial plain.

- **Refined understanding of the current condition of HNWR-1.** HNWR-1 will currently supply enough water of sufficient quality to supply the groundwater remedy at the nominal design flow rate of 450 gallons per minute (gpm), but not the maximum flow rate of 900 gpm. While the construction of the well was sufficient for its original intent (irrigation), it is not sufficient for long-term daily operation as a reliable element of the groundwater remedy. Due to the design and construction of the well the options for aggressive and effective well maintenance are limited. Further, operational flexibility to lower the pump and generate more flow is limited by the smaller diameter of the lower portion of the well.
- **Aquifer quality and well performance at Site B.** The Site B well will supply enough water to support the maximum designed remedy flow rate and the well construction allows optimal flexibility for operation (i.e., pump depth) and maintenance options; however, based on current well construction and operation during testing, the water quality is currently not optimal.
- **EIR Mitigation Measures WATER-1.** Constant-rate extraction tests conducted for a duration of 72 hours at both HNWR-1 and the Site B well suggest that neither will substantially adversely affect the production rates of existing nearby wells (see EIR Mitigation Measure WATER-1, Addendum No. 1).

Following is the recommended path forward for establishing a reliable freshwater supply for the groundwater remedy:

1. Conduct a depth-specific characterization of the Site B well to evaluate the potential for well modifications to improve water quality.
2. Install a new well at the HNWR-1 Site to provide the primary source of freshwater for use as part of the groundwater remedy.
3. Design the infrastructure required to plumb and operate both the new well at the HNWR-1 Site and the Site B well in order to provide maximum flexibility and reliability in the remedy freshwater supply.

1.0 Introduction

Pacific Gas and Electric Company (PG&E) is implementing the selected groundwater remedy for chromium in groundwater at the PG&E Topock Compressor Station (TCS, or the Compressor Station) in San Bernardino County, California. Remedial activities at the Topock site are being performed in conformance with the requirements of the Resource Conservation and Recovery Act (RCRA) Corrective Action pursuant to a Corrective Action Consent Agreement (CACA) entered into by PG&E and the California Department of Toxic Substances Control (DTSC) in 1996, as well as the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) pursuant to pursuant to a Remedial Design/Remedial Action Consent Decree between the United States and PG&E, entered by the United States District Court for the Central District of California on November 21, 2013.

As an element of the final groundwater remedy design, freshwater sources, including groundwater supply wells and the Colorado River, have been considered for use during remedy operation. The average and maximum volume of freshwater required for remedy operation is estimated to be 450 and 900 gpm, respectively, based on groundwater modeling. In the *Basis of Design Report/Intermediate (60%) Design for the Final Groundwater Remedy* (CH2M HILL, 2013b), PG&E presented a plan to obtain freshwater from a well on HNWR—well HNWR-1. This evaluation was conducted based on concern raised by DTSC in their August 8, 2012 (DTSC, 2012) letter regarding water quality from the proposed remedy freshwater source.

This technical memorandum summarizes the activities conducted and associated findings for the evaluation of alterative freshwater sources as defined in the Work Plan (CH2M HILL, 2013b).

1.1 Approvals and Authorizations

The Topock Alternative Freshwater Source Evaluation was executed in conformance with the following approvals and authorizations:

- DTSC acceptance of the Work Plan (CH2M HILL, 2013b) and approval for implementation subject to conditions set forth in the letter (DTSC, 2012), which included Mitigation Measures adopted by the certified Final Environmental Impact Report (DTSC, 2011) as specified in the EIR Addendum (No. 1) for the Alternative Freshwater Source Evaluation.
- U.S. Department of Interior [DOI], Bureau of Land Management [BLM], U.S. Fish and Wildlife Service [USFWS], and Bureau of Reclamation [Reclamation] acceptance of the Work Plan (CH2M HILL, 2013b) and approval for implementation subject to the conditions set forth in the letter (DOI, 2013).
- HNWR acceptance of the Work Plan (CH2M HILL, 2013b) and approval for implementation subject to the conditions set forth in the email to Yvonne Meeks of PG&E (HNWR, 2012).

1.2 Coordination with Agencies and Tribes

Immediately prior to conducting any ground disturbing activities, a project initiation meeting was held at the Topock Compressor Station on October 2, 2013. During this meeting, representatives from PG&E, the regulatory agencies and Tribes discussed the details of the planned fieldwork, biological, paleontological, cultural, and historical sensitivities associated with the project area, and conducted a walk of the fieldwork sites. During work, in addition to discussion during routine project meetings, three conference calls with the TWG were held to provide updates on project activities and provide preliminary summaries of the data collected. These calls were held on November 4, 2013, January 29, 2014, and February 28, 2014. In addition to these calls, options for freshwater supply for the remedy and conceptual pipeline routing and infrastructure that would be associated with the potential freshwater supply well(s) was discussed during the March 19, 2014, TWG meeting. Tribal monitors participated throughout the fieldwork and were provided with routine field schedule updates.

1.3 Technical Memorandum Organization

The remainder of this technical memorandum is organized in the following manner:

- **Section 2.0** summarizes the field activities conducted throughout the evaluation.
- **Section 3.0** present the analysis of the data collected during the evaluation, including the results of laboratory analysis of groundwater samples, and analysis of hydraulic testing data.
- **Section 4.0** summarizes the PG&E recommended path forward for establishing a freshwater supply for the groundwater remedy.
- **Section 5.0** provides a list of works cited in this technical memorandum.

2.0 Summary of Field Activities

Field activities were conducted in three general phases including exploratory drilling and data collection, well construction and development, and well and aquifer testing. All project activities were performed under the supervision of both a California and Arizona Professional Geologist. This section describes the details of each element of work conducted.

2.1 Site Access, Preparation, Compliance Monitoring, and Security

An onsite biologist conducted a pre-construction survey before work began. Biological monitoring was conducted daily throughout fieldwork by a field contact representative (FCR) that was trained by the biologist prior to the beginning of work. The post-construction surveys for each investigation site is pending and will be completed following fence installation at Site B (scheduled for April 2014) or after any additional

fieldwork (see Section 4). After complete, the pre- and post-construction survey data will be used to assess and document compliance with the Programmatic Biological Assessment (PBA) (CH2M HILL, 2007). The results of these surveys will be provided a biological resources completion report, which is scheduled for submittal to BLM and the Havasu National Wildlife Refuge (HNWR) 60 days after the completion of fieldwork.

An onsite archaeologist and an onsite paleontologist conducted a pre-construction survey before work began for cultural and paleontological resources, respectively. All site activities were monitored daily by an onsite archaeologist. Tribal monitors, which were invited to observe all site activities, did monitor many of the activities. In addition, a paleontologist was present at the beginning of ground-disturbing activities and provided paleontological awareness training for all site personnel. The paleontologist was on-call throughout the fieldwork, but was not contacted by the field team as paleontological resources were not observed during drilling.

Access for drilling and associated equipment was established at both the HNWR-1 Site and Site B along access routes identified in the Work Plan (CH2M HILL, 2013b) by importing gravel from local quarries. The existing land surface at the work sites was not graded. Prior to work, both sites consisted of flat, sandy areas that were previously disturbed by HNWR activities as part of an ongoing re-vegetation effort. Site B was devoid of vegetation. The HNWR-1 Site was sparsely vegetated with Russian thistle, which is viewed by HNWR as an invasive, nuisance species. The Russian thistle in the HNWR-1 Site work area was removed at the direction of the HNWR and as directed in the field by the onsite biologist. No listed species or nesting birds were observed during the pre-activity or post-activity surveys.

After the work areas were established, temporary fencing was installed to control site access. Onsite security was utilized to monitor the work areas during non-working hours. No incidences of unauthorized site access were detected during any of the work phases.

Each drilling location was surveyed for underground utilities prior to work. The surveys included participating in the Arizona Blue Stake mark-and-locate program and using surface geophysical techniques typically used for utility location (e.g., radio frequency line location tool).

Project activities were conducted in compliance with the items identified in Attachment B of the Work Plan (CH2M HILL, 2013a), which includes compliance with Applicable and Relevant or Appropriate Requirements, the PBA (CH2M HILL, 2007), the Programmatic Agreement (BLM, 2010), and the Cultural and Historic Properties Management Plan (BLM, 2012). Compliance monitoring activities associated with the EIR Addendum No. 1 Mitigation Measures Reporting Program (MMRP), which is also included in Attachment B to the Work Plan (CH2M HILL, 2013a), were conducted continuously during fieldwork associated with the Work Plan (CH2M HILL, 2013b) and are documented in the quarterly compliance reports, which are available on the DTSC website for the Topock Project Site. While discussing Site B well construction activities during the February 12, 2014, Consultative Working Group (CWG) meeting, representatives from the Tribes raised a question whether the disturbance associated with filling a shallow slump around the conductor casing (see Section 2.3) was addressed by the MMRP for EIR Addendum No. 1. While the slump was an unplanned result of drilling, the total volume of the subsurface Site B well disturbance is still less than that provided for in the EIR Addendum. Based on the depth and diameter assumptions in the Work Plan (CH2M HILL, 2013b), the total “planned volume” of the well is approximately 316 cubic yards. Based on final well construction, including the estimated dimension of the slump that was filled, the total subsurface volume disturbed by Site B drilling and well installation activities is approximately 262 cubic yards.

2.2 Exploratory Drilling, Data Collection, and Borehole Decommissioning

At each Site B and the HNWR-1 Site, one exploratory borehole was installed to a depth of 400 feet bgs to facilitate collecting lithologic and zone-specific groundwater samples. Each borehole was drilled using the dual-rotary method (using a Foremost DR-24 drill rig), which rotates both an outer, primary casing and the drill string (attached to the drill bit), independently. This method injects compressed air down the drill string, and out the bit, to return drill cuttings from the bottom of the borehole to the ground surface within the

inside of the primary casing. The primary casing remains in place as the borehole is drilled to maintain borehole stability. An 8-inch (nominal diameter) primary casing was used to drill both exploratory boreholes. No chemical additives were used during drilling. Freshwater was introduced to the borehole at various times during drilling at both sites to counteract heaving conditions (i.e., the water was used to provide hydraulic head within the drill casing to counteract formation materials moving up into the drill casing). Freshwater used during drilling was obtained from the Golden Shores Water Company. Drill cuttings recovered during drilling were logged in accordance with the methods and procedures identified in the Work Plan (CH2M HILL, 2013b). The lithologic logs for both boreholes are provided in Attachment A.

After the water table was reached, zone-specific groundwater samples were collected from the borehole approximately every 50 feet to assess changes in water quality with depth and qualitative changes in borehole capacity. Eight zone-specific groundwater samples were collected from each of the exploratory boreholes for laboratory analysis as defined in the Work Plan (CH2M HILL, 2013b). With the exception of the sample collected from 400 feet in the HNWR-1 Site borehole, which was collected using a bailer because the zone did not produce enough water to be pumped, each sample was collected by removing the drill string from within the primary casing and operating a submersible pump within the borehole (i.e., inside the primary casing). Water quality measurements were monitored at the surface (e.g., specific conductance, pH, oxidation-reduction potential) throughout purging for sample collection. Dissolved oxygen was not measured during the collection of groundwater samples from the borehole because the drilling method injects large volumes of air while drilling, which aerates the groundwater and obscures the natural distribution of dissolved oxygen in the groundwater. All groundwater samples were analyzed in accordance with the Work Plan, with all samples being analyzed for Title 22 (CAM 17) metals, silica, fluoride, and nitrate. A subset of samples (approximately half of those collected) were analyzed for the list of water quality parameters that were used to previously characterize the existing HNWR-1 well, including CAM 17 metals, perchlorate, petroleum hydrocarbons, pesticides, polyaromatic hydrocarbons, polychlorinated biphenyls, herbicides, chloride, sulfate, nitrate, nitrite, fluoride, bromide, phosphate, general minerals, total organic carbon, pH, gross alpha and beta, and stable isotopes of hydrogen and oxygen. Specifically, this included the samples from 100, 200, and 300 feet bgs in both the HNWR-1 Site borehole and Site B, and at 400 feet bgs in the Site B borehole only. While a sample for the “longer list” laboratory analysis was planned for the 400 feet bgs sample in the HNWR-1 Site borehole, this sample was only analyzed for the “shorter list” due to sample volume constraints. Even though the zone specific samples were analyzed by a certified laboratory, the data are considered screening level quality because of the method of sample collection (i.e., pumping or bailing from an open borehole during construction).

After each of the exploratory boreholes were drilled to total depth and the final zone-specific groundwater sample was collected, the 8-inch primary casing (exploratory casing) was left in place pending discussion of the exploratory data with the TWG and decision on the next steps for the evaluation. During this time, each casing was secured at the surface by welding a cap over the top and placing hydrated bentonite clay around casing where it interfaced with the surface soils. This approach to temporarily securing the exploratory casing was discussed with and approved by ADWR. Following discussion of the exploratory data with the TWG on November 4, 2013, the exploratory casing at Site B was removed and the borehole was subsequently reamed for the installation of the Site B well (see Section 2.3). Subsequent to the installation of the Site B well, the exploratory casing at the HWNR-1 Site was removed and the borehole was decommissioned in accordance with the Work Plan (CH2M HILL, 2013b). Specifically, the borehole was decommissioned in accordance with variance option “Alternative 4” of ADWR’s *Well Abandonment Handbook* (ADWR, 2008). The borehole was decommissioned by backfilling from total depth (400 feet) to 22 feet bgs with pea gravel. The interval from 2 to 22 feet bgs was sealed using cement bentonite grout (installed via positive pressure tremie), and the upper most 2 feet was backfilled with granular material from the existing site area (i.e., drill cuttings from the borehole and surface soil adjacent to the borehole).

2.3 Site B Well Construction and Development

Following joint direction received from DTSC and DOI (DTSC, 2013b) the exploratory boring at Site B was reamed for the installation of a new well. Well design was based on evaluation of lithologic data from recovered drill cuttings, and the results of field measurement and laboratory analysis of zone-specific groundwater samples. Borehole drilling, well construction, and well development activities were conducted from November 2013 to February 2014. The materials and methods used for constructing and developing the Site B well are presented in this section. A well construction diagram is provided in Attachment A-1. Although drilling and well installation activities conducted as part of the Work Plan (CH2M HILL, 2013b) are exempt from the requirement to obtain well installation permits from the ADWR pursuant to the CERCLA Section 121(e)(1) permitting exemption, NOI to install wells at both the HNWR-1 Site (used only for the exploratory borehole at this time) and Site B were filed (provided in Attachment A) and the substantive requirements associated with the approved NOIs were followed.

The Site B well was drilled and constructed using the dual-rotary drilling method (using a Foremost DR-40 drill rig) as follows:

1. **Removed the exploratory casing.** The 8-inch exploratory casing was pulled from total depth (400 feet bgs) using the drill rig. The portion of the exploratory borehole from 400 to 320 feet bgs was sealed using cement bentonite grout (installed via positive pressure tremie). The remainder of the borehole was left open and allowed to collapse since this portion would be subsequently reamed for well construction.

2. **Installed the conductor casing.** A conductor casing was installed to stabilize the upper portion of the borehole, provide a primary surface seal (per ADWR well standards), and isolate the completed well from shallower groundwater. A 31-inch-diameter (nominal) borehole was drilled to 77 feet bgs, and a 24-inch (nominal) mild-steel conductor casing was installed (all joints were welded). The annulus between the conductor casing and the borehole wall from 77 feet bgs to ground surface was sealed using cement bentonite grout (installed via positive pressure tremie).

3. **Drilled the borehole for well construction.** After the seal for the conductor casing had cured, a 21-inch-diameter (nominal) borehole was drilled out the bottom of the conductor casing to a total depth of 325 feet bgs, which is 5 feet into the top of the sealed portion of the exploratory borehole. As previously discussed, a shallow surface slumping event occurred around the outside of the conductor casing during drilling. While not desirable, this is not uncommon when drilling with compressed air. The slump resulted in a shallow void around the outside of the conductor casing in the vadose zone (the bottom of the void was confirmed near the interface of the water table at approximately 19 feet bgs using a tag line). The diameter of the void at the ground surface was approximately 5 to 7 feet. It is estimated that the slump was caused by zones of weakness created in the early stages of borehole drilling for conductor casing installation (a condition exacerbated by the fine-grained nature of the shallow vadose zone). These zones of weakness were bridged during sealing of the conductor casing, and continued to settle during the drilling of the 21-inch borehole until the slumping event occurred. The slump was stabilized using cement bentonite grout that was poured from the ground surface.

4. **Installing the well casing and annular materials.** After the 21-inch borehole was drilled to total depth, the well casing was installed within the primary drill casing. The well casing and screen are 14 inches in diameter and composed of 316L stainless steel (all joints were welded). All well screen is wire wrapped with 0.090-inch open spacing between wires. Filter pack material was installed through the primary casing, and all sealing materials were installed via tremie within the primary drill casing, which was removed from the borehole in stages as annular materials were installed around the well casing. All filter pack annular material is composed of Tacna 4x10 gradation sand. The well was constructed with the following casing and screen intervals (described from the bottom of the well to the ground surface):

    - 320 to 305 feet bgs – cased with a welded cap on the bottom and filter sand in the annular space (this section comprises the sump).

- 305 to 265 feet bgs – screened with filter sand in the annular space.
- 265 to 245 feet bgs – cased with an intermediate annular seal composed of hydrated bentonite pellets from 260-250 feet bgs. This section provides operational flexibility in the event the lower screened section needs to be isolated, or sealed, and can also be used as a lower pump chamber.
- 245 to 195 feet bgs – screened with filter sand in the annular space.
- 195 to 185 feet bgs – cased with filter sand in the annular space. This section provides operational flexibility in the event an intermediate pump chamber is determined beneficial to operation.
- 185 to 145 feet bgs – screened with filter sand in the annular space.
- 145 feet bgs to ground surface – cased with the annular space sealed from 120 feet bgs to the ground surface with cement bentonite grout. The section is the primary pump chamber and also provide a secondary surface seal. A 2-inch-diameter, 304L stainless steel gravel feed tube was installed in the annular space from 130 feet bgs to the ground surface.

5. **Completed the well head.** The stainless steel well casing (i.e., production casing) was completed approximately 3 feet above ground surface, and sealed with a blank flange plate (bolted with gasket). The gravel feed tube was also completed above grade and sealed with a 2-inch compression cap. The mild steel conductor casing was extended above the production casing with a hinged cap that is secured with a padlock, which is similar to other wells associated with the Topock Remediation Project.

A well construction diagram summarizing this information is provided in Attachment A-1.

After the secondary seal installed between the conductor casing and the production casing had cured, development of the well began. Development was initially conducted using the drill rig using a dual-swab air lift tool. This high-energy development method uses compressed air to extract groundwater from the well. The dual-swab tool uses a steel casing with openings along a 20-foot interval and rubber gaskets (swabs) at the top and bottom of the 20 foot section to focus the pumping energy along specific intervals of well screen. Following air lift development, a line-shaft pump was installed in the well and used to surge the well at multiple flow rates. Sand production and water quality measurements (e.g., specific conductance, pH, oxidation-reduction potential, and dissolved oxygen) were monitored on the effluent water at the surface during well development. Approximately 385,000 gallons were removed during initial air-lift development, and approximately 2,270,200 gallons were removed during pump development.

Following construction, development, and testing (see Section 2.5), in-well video and plumbness surveys were conducted to verify well details and condition on February 20, 2014. The video survey confirmed the well construction details outlined above and that the well screen, casing, and welded joints were in good condition (a summary of the Site B video survey is provided in Attachment A-1). The video log also confirmed that some sand and silt had settled in the sump during final development and testing activities. A portion of the material was subsequently removed by bailer, but some of the more densely compacted material will need to be removed by air-lift at a later date (i.e., at the time the well is put into operation). An in-well gyroscope was used to verify that the well casing was plumb.

2.4 HNWR-1 Well Construction and Condition

A video survey of the existing HNWR-1 well was conducted on October 21, 2013, to verify well construction details and condition (a summary of the HNWR-1 video survey is provided in Attachment A-2). The existing submersible pump was temporarily removed from the well to provide access for the down-hole camera, and was re-installed immediately following the survey. The video survey in combination with well installation notes previously provided by the HNWR confirms that the well was constructed with a 10-inch-diameter, mild steel well casing from 2.75 feet above ground surface to approximately 118.5 feet bgs. The 10-inch casing shows moderate to heavy scaling below the water table and has been perforated (apparently post-installation using a roller perforator) from approximately 90.5 feet bgs to 118.5 feet bgs, where the well reduces to 8 inches in diameter (based on visual estimation, a caliper survey was not conducted) and the

material changes to stainless steel, wire-wrap screen. An adapter section of the reduced diameter is in place from approximately 118.5 to 119.5 feet bgs, and the stainless steel, wire-wrap screen was observed to a depth of approximately 156 feet bgs where soft fill prevented further video confirmation; however, the camera was lowered to a total depth of approximately 165 feet bgs before being refused (this depth was difficult to verify given the fill in the bottom of the well). The well screen is noted to be partially plugged based on the video survey.

Interpretation of this video survey in combination with available well installation notes suggests that the 10-inch well casing was installed by drilling with a casing advance method to a total depth of 160 feet bgs. A 40-foot-long screen section was then fabricated (two 20-foot screen sections welded together, and presumably with a cap welded to the bottom) with a 6-inch K-packer (i.e., a series of rubber rings mounted onto a section of steel pipe) welded to the top of the screen section. The screen assembly was then landed on the bottom of the borehole at 157 feet bgs (it is inferred that there was approximately 3 feet of heaved formation within the 10-inch casing). With the screen assembly in the bottom of the borehole, the 10-inch casing was retracted with the drill rig to expose the screen assembly, leaving approximately 2.3 feet of 10-inch casing below the K-packer. The installation of filter sand or gravel is not noted in the installation notes, and it would not be possible to have installed filter pack material given this construction method. Given the casing advance drilling method, the perforations in the 10-inch must have been cut with the casing in situ, otherwise the casing would have failed during drilling. The driller's notes indicated that a temporary surface casing (i.e., conductor casing) was used then pulled after the 10-inch casing was in its final position (with the screen exposed), and "grouted up." A conceptual well construction diagram for HNWR-1 that summarizes this inferred construction is provided in Attachment A-2.

While this well was adequate for the irrigation purpose for which it was designed, it is not adequate for long-term operation as part of the groundwater remedy freshwater supply. The well construction severely limits the options available for future well rehabilitation, and the effectiveness of rehabilitation overall. The lack of filter pack and the relatively large aperture perforations in the 10-inch casing are especially problematic as formation material will move readily into the well when surged. The construction details for the surface seal, which protects the well for infiltration of fluids from the surface, are not completely known.

2.5 Well and Aquifer Testing

Hydraulic testing was performed at both the existing HNWR-1 well and the Site B well to assess well performance and estimate aquifer properties. Step-rate tests were conducted in both wells to estimate the upper end of flow that could be sustained during the subsequent constant-rate tests conducted in each well. All groundwater discharged during the well tests was surface irrigated to the area designated in the Work Plan (CH2M HILL, 2013b) (see Section 2.6). The duration of both constant-rate extraction tests was constrained to 72-hours so that the irrigation area could be managed with zero run-off.

Effluent water quality measurements (e.g., specific conductance, pH, oxidation-reduction potential, and dissolved oxygen) were monitored in the field during all well tests. Dissolved oxygen was not measured during the HNWR-1 step-rate test due to a malfunctioning sensor. Water quality samples for laboratory analysis were collected from the pump effluent during both constant-rate tests to assess if water quality changed over time. Samples were collected during the tests at 1 hour, 6 hours, 12 hours, 24 hours, 48 hours, and 72 hours after the start of the test. All samples were analyzed in accordance with the Work Plan (CH2M HILL, 2013b). In addition to field parameters, groundwater samples were analyzed for CAM 17 metals, silica, fluoride, and nitrate. In addition, as requested by the TRC during the January 29, 2014, conference call with the TWG, all groundwater samples were analyzed for stable isotopes of hydrogen and oxygen. Samples from the beginning and end of the test (1 hour and 72 hours) were analyzed for a longer list of analytes, including CAM 17 metals, perchlorate, petroleum hydrocarbons, pesticides, polyaromatic hydrocarbons, polychlorinated biphenyls, herbicides, chloride, sulfate, nitrate, nitrite, fluoride, bromide, phosphate, general minerals, total organic carbon, pH, and gross alpha and beta.

Pressure transducers were utilized in several observation wells in the project area to observe potential effects of pumping at each of the wells during the constant-rate tests. In addition to the pumping wells (the Site B well and HNWR-1), monitoring the level of the Colorado River (I-3 gauging station) and barometric pressure, the following observation wells and surface water bodies were instrumented during testing (listed roughly from east to west): monitoring well near the Serrano supply well, Topock-2 (operated by Southwest Water Company), Topock-3 (operated by Southwest Water Company), GSRV-2, Topock-66 (test well for fire water supply), MW-55-120, MW-55-45, Catfish Paradise (surface water body north of South Dike), Lost Lake (surface water body south of South Dike), MW-54-85, MW-54-140, MW-54-195, and MW-49-195 (on the California side of the Colorado River). The location of these wells and surface water bodies are presented on Figure 1.

Testing details specific to each well are summarized in the following subsections.

HNWR-1. A step-rate extraction test was conducted at HNWR-1 on October 16, 2013, and a 72-hour constant-rate extraction test was conducted from February 11 to 14, 2014. Both tests were conducted using the existing electric submersible pump (Grundfos 800S750-3 pump with a 75-horsepower motor), which was installed with the intake at approximately 88 feet bgs (approximately 3 feet above the top of the well casing perforations). The step-rate test consisted of six 90-minute steps with the following average flow rates: 278 gpm, 382 gpm, 472 gpm, 557 gpm, 658 gpm, and 767 gpm. A seventh step was attempted at 875 gpm (maximum pump flow) but the pump began to cavitate after approximately 30 minutes, indicating that water level drawdown in the well had dropped below the minimum operating head required above the pump. Based on analysis of the step-rate extraction test, a flow of 700 gpm was chosen for the constant-rate test. A plot of the drawdown data collected during the HWNR-1 step-rate test is provided in Figure B-1 in Attachment B. HNWR-1 is located approximately 750 feet from the operational Topock-2 and -3 supply wells, which are operated by Southwest Water Company to provide freshwater to the Topock Compressor Station, Topock-66 restaurant, and nearby residences. Prior to the beginning of the HNWR-1 constant-rate test, project staff coordinated with the Southwest Water Company to fill available storage on the compressor station and for the residences/Topock-66 restaurant so that well operation could be minimized during the HNWR-1 testing period.

Site B. A step-rate extraction test was conducted at the Site B well on February 7, 2014, and a 72-hour constant-rate extraction test was conducted from February 7 to 10, 2014. Both tests were conducted using a line-shaft turbine pump that was temporarily installed for well development and testing. The intake of the test pump was located at approximately 138 feet bgs (approximately 7 feet above the top of the well screen). The step-rate test consisted of six 80-minute steps with the following average flow rates: 507 gpm, 694 gpm, 911 gpm, 1,101 gpm, 1,292 gpm, and 1,494 gpm. A plot of the drawdown data collected during the Site B step-rate test is provided in Figure B-2 in Attachment B. Based on analysis of the step-rate extraction test and projecting the amount of water could be applied over time to the irrigation area (based on irrigation that had been conducted to date), a flow of 1,000 gpm was chosen for the constant-rate test.

2.6 Management of Material Generated during Evaluation

Three types of materials were generated during fieldwork: drill cuttings, purged groundwater, and trash, all of which were managed in accordance with the Work Plan (CH2M HILL, 2013b). Drill cuttings and purged groundwater were managed in accordance with site-specific and regulatory practice for groundwater supply well drilling. Because this work was conducted as part of a CERCLA response action, implementation plan activities conducted onsite were covered under the permit exemption codified in Section 121(e)(1) of CERCLA. While the permit exemption applies to the administrative or procedural elements (e.g., preparing and submitting permit applications and obtaining permits), the substantive requirements of the applicable laws remain. Groundwater discharge and drill cuttings were managed in compliance with the substantive requirements of Aquifer Protection General Permit 1.04, as authorized by Arizona Administrative Code Section R18-9-B301(D).

Drill cuttings were diverted from the cuttings return pipe on the rig using a cyclone that was staged over the top of a roll-off bin. From the roll-off bin all drill cuttings were spread to the ground surface adjacent to the borehole. Chemical additives were not used during drilling, therefore cuttings sampling was not necessary to determine suitability for discharge to the ground surface. Drill cuttings were not discharged to any jurisdictional areas. Clay was recovered in the drill cuttings from both boreholes. In accordance with the Work Plan (CH2M HILL, 2013b), the clay material was gathered and separated from the other drill cuttings for storage on dye-free cotton muslin fabric and labeled. The material was recovered from the cuttings bin as many small clay balls, which were subsequently aggregated into a larger ball that was approximately the size of a soccer ball. The material was securely stored at the work site, and the agencies and Tribes were informed of the clay. The material was subsequently managed by the project archaeologist in coordination with the Tribes.

Purged groundwater was generated during drilling, well development, and well testing. Water generated during drilling and air-lift development (see Section 2.3) was discharged to the ground surface in the same area as the drill cuttings. Water was generated at a higher rate during pump development and well testing. This water was surface irrigated to the area designated in the Work Plan (CH2M HILL, 2013b). The water was pumped through a temporary, aboveground conveyance pipeline to as many as 12 sprinklers in the irrigation area (see Figure 2). During key development activities, discharge was irrigated directly to the ground without the use of a sprinkler to avoid discharge pressure limitations associated with the sprinkler equipment; however, all discharge activities were conducted in a manner that did not promote scouring or erosion of the irrigation area. A total volume of approximately 10.5 million gallons was discharged to the irrigation area during pump development at Site B and all well testing activities at both wells. Purged groundwater was neither discharged nor allowed to run-off to jurisdictional areas, the Colorado River, nor Arizona County Highway 10.

Incidental trash was removed from the work area daily and was transferred to a standard trash bin at the TCS for offsite disposal.

3.0 Results of the Evaluation

This section presents the analysis of data collected during the activities detailed in Section 2. Section 4 discusses the integration of all available data from this evaluation, and associated recommendations for the path forward in establishing a freshwater supply for the groundwater remedy.

3.1 Exploratory Data

This section presents the analysis of lithologic data collected during drilling, and the results of screening level groundwater samples collected from the initial exploratory boreholes.

Lithology and Hydrostratigraphy. Based on data collected from the exploratory boreholes, a single unconsolidated aquifer was drilled at both locations that is comprised largely of well graded gravels with sand. A combination of finer-grained sands and slits and gravel is observed in the upper 40 feet of the HNWR-1 Site and the upper 100 feet of Site B. Within this interval, a layer of lean clay was encountered at Site B between 70 and 80 feet bgs. This finer-grained material is likely a combination of overbank deposits from the Colorado River and alluvial material sourced from Sacramento Wash. Below these finer-grained intervals, the lithology encountered was predominantly comprised of fluvial river gravels with sand. Both boreholes are located within the large fluvial plain of the pre-dam era Colorado River, and the detailed drilling logs describe these clean fluvial deposits at a greater frequency and thickness than the fluvial deposits on the California side of the River, which represents the thin western edge of the fluvial plain. Bedrock was not encountered at either the HNWR-1 Site or Site B; however, low penetration rates during drilling the deeper portion of the HNWR-1 Site exploratory borehole might be an indication that the total depth of this borehole was closer to bedrock that the Site B borehole (see also specific conductance data from the deeper portion of the HNWR-1 Site borehole, and the limited groundwater recovery at the bottom of the borehole). The additional lithologic data collected during this evaluation has been added to the conceptual cross-section that was included in the Work Plan (CH2M HILL, 2013b) (see Figure 3).

The water table was encountered at approximately 9 and 19 feet bgs at the HNWR-1 Site and Site B, respectively (based on water level data collected from the HNWR-1 and Site B wells), and the ground surface at Site B is approximately 8 feet higher than at the HNWR-1 Site. The HNWR-1 well has been surveyed for elevation, but the survey for the Site B well is pending; therefore, detailed comparison of groundwater elevation between the two sites (accounting for river level influence) cannot be completed at this time. Regardless, the groundwater elevation at the two sites appears to be very similar.

Screening-level Groundwater Samples. This section presents the results of field water quality measurements (Table 1) and laboratory analysis of the 8 screening level, zone-specific groundwater samples collected from the HWNR-1 Site and Site B exploratory boreholes (Tables 2 through 9).

Field Measurements. Field water quality measurements monitoring during sample collection, included specific conductance, temperature, pH, oxidation-reduction potential, and turbidity, as well as depth to water within the primary drill casing during purging. Specific conductance measurements indicate a change in water type in both boreholes with higher specific conductance (saltier) water occurring deeper in the borehole, and a lower specific conductance (less salty) water occurring in the shallower intervals. This transition was observed between the 350- and 400-foot-bgs samples at Site B, and between the 250- and 300-foot-bgs samples at the HNWR-1 Site. Therefore, the thickness of fresh (less salty) water at Site B is approximately 100 feet greater than at the HNWR-1 Site. Based on measurement of ORP, the deeper, saltier water in each borehole tends to be reduced while the shallower, fresher water is aerobic (i.e., positive oxygen-reduction potential). This is consistent with the conceptual site model of shallower groundwater being a combination of river water and infiltration from Sacramento Wash, with the older, saltier water along the bottom of the basin. This trend is observed in both alluvial and bedrock wells and is consistent with the theory that in this lower portion of the Mohave basin, older connate water is upwelling from the deeper portions of basin. During the eons that it could take for groundwater to move through the basin, the salts are leached from the rocks, increasing specific conductance, and dissolved oxygen is lost through reactions with reduced mineral species.

The temperature of the groundwater in both boreholes ranged from approximately 32 to 42 degrees Celsius (approximately 90 to 107 degrees Fahrenheit). Measurements collected from shallow to deeper within each borehole indicate increasing temperature with depth. The measurement collected from the deepest sample in the HWNR-1 Site borehole was lower than would be expected based on the trend of measurements from shallower samples. This is because this sample was collected with a bailer, while all the other samples were collected using a submersible pump. Variations in temperature measurements can be an artifact of submersible pump operation to purge the groundwater. In general, pumping with less hydraulic head above the pump (i.e., more drawdown) will result in a temperature measurement that is biased higher. For example, the majority of temperature measurements from the HNWR-1 Site borehole are approximately 36 degrees Celsius while pumping with approximately 80 feet of drawdown. In the Site B borehole, similar pumping conditions resulted in a similar temperature measurement, while lower temperature measurements were observed when pumping with less drawdown. Heat from the drilling tools can also create variations in temperature from one measurement interval to the next. Section 3.1 discusses the temperature measurements taken while pumping within the wells, which removes some of this variability.

Measurements of pH were consistent between both boreholes, ranging from approximately 7.5 to 8.5, which is consistent with measurements throughout the project area.

Metals. In general, concentrations of metals observed in zone-specific samples were similar between the two boreholes. Dissolved arsenic concentrations ranged from non-detect to 12 micrograms per liter (μg/L) at the HNWR-1 Site, and from 0.97 to 13 μg/L at Site B. The detected ranges of chromium were also similar between the two boreholes with a range of non-detect to 11 μg/L at the HNWR-1 Site, and non-detect to 16 μg/L at Site B. Samples from the zones that correspond to the deeper, saltier water have very low to non-detect concentrations of hexavalent chromium, which is consistent with the reducing conditions discussed in

the field measurements above. Similarly, dissolved arsenic concentrations are also very low to non-detect in these samples suggesting a different water type.

Organics. Organic analyses included perchlorate, total petroleum hydrocarbon (TPH), pesticides, polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and herbicides. All results for perchlorate, pesticides, PAHs, PCBs, and herbicides were non-detect. TPH as diesel was detected at concentrations slightly above the reporting limit in the 100- and 200-foot-bgs samples from the Site B borehole (58 and μg/L, respectively), and TPH as motor oil was detected slightly above the reporting limit in the 400-foot-bgs sample from the same borehole (53 μg/L). These TPH detections are believed to be associated with the lubricants used in the air compressor or on the drilling tools, and would not be expected to persist.

Other Constituents. Review of the results of other analyses including contract laboratory program (CLP) inorganics and general chemistry indicates that the samples from the depths that correspond to the deeper, saltier water have higher concentrations of calcium, iron, magnesium, potassium, sodium, chloride, and sulfate. The concentration of nitrate as nitrogen was particularly elevated (200 milligrams per liter (mg/L)) in the shallowest sample collected from the Site B borehole. This concentration is attributed to nitrogen released from the decay of the dense vegetation that covered this area for many years but was burned prior to the initiation of the HNWR Re-vegetation Project.

Analyses of the zone-specific samples for stable isotopes of hydrogen and oxygen indicate a consistent isotopic signature within each borehole, and across the two boreholes. In the *Final RCRA Facility Investigation/Remedial Investigation Report* (Final RFI/RI Report) (CH2M HILL, 2009), stable isotopes of oxygen and hydrogen were used to generally identify three water groups: 1) river water and river-influenced groundwater, 2) local alluvial groundwater, and 3) industrial water from historical facility discharges. The groups are intermixed to varying degrees. When compared with the isotopic signature of other wells in the project area, the samples from the exploratory boreholes correspond with alluvial and fluvial non-plume wells, which is consistent with the conceptual model of the aquifer for this area.

3.2 Aquifer Testing Data

The constant-rate extraction tests at HNWR-1 and Site B were each conducted for 72 hours. Drawdown at HNWR-1 and Site-B is shown in Figures B-3 and B-4 in Attachment B. The HNWR-1 test was conducted at flow rate of 700 gpm, which maintained approximately 44 feet of water level drawdown in the well. Similarly, the Site B test was conducted at flow rate of 1,000 gpm, which maintained approximately 60 feet of drawdown in the well. During the Site B test, the drawdown in the well recovered approximately 2 feet throughout most of the test duration; however, the water level stabilized during the final hours of the test. Because the recovery trend eventually stabilized, this recovery is attributed to increased well efficiency over most of the testing period and not recharge associated with the infiltration of surface irrigated test water, which would be expected to show an exponential recovery curve. This slight draw-up of the water level in Site B during testing did not have an adverse effect on analysis of the data.

The water level data collected during the HNWR-1 and Site B constant-rate extraction tests were downloaded from the transducers and compiled following completion of the tests. Pumping at HNWR-1 produced measurable drawdown and recovery in the Topock-2 and Topock-3 wells (less than 1 foot) (Figure B-5 in Attachment B). Pumping from the Site B well produced measurable drawdown in the HNWR-1, Topock-2, and Topock-3 wells. The Topock-2 well began pumping approximately 7 hours before the conclusion of the 72-hour Site B test and remained pumping until several hours after the conclusion of the test. This prevented the Topock-2 and Topock-3 well data from being used for aquifer test analysis after this time, but usable data were collected over the majority of the test period.

Data from monitoring well clusters MW-54 and MW-55, MW-49-135, and data from the Topock-66, and Serrano wells were corrected using the U.S. Geological Survey deconvolution software (Halford, et al, 2012) to filter out the influence of river and barometric fluctuations on these wells. Inspection of deconvoluted data from these wells indicated no measurable drawdown from either the Site B or HNWR-1 test.

Hydrographs with raw (uncorrected) data and corrected data from these wells are presented in Figures B-6 through B-10 in Attachment B. Initial review of the uncorrected data at MW-55 and Topock-66, as discussed during the February 28 conference call with the TWG, indicated potential drawdown of up to 0.2 feet, though final data corrected for the influence of the river indicated no measureable drawdown from either the Site B or HNWR-1 test. The Site B well data recorded during the HNWR-1 test were also deconvoluted, and these data did not exhibit measurable drawdown (Figure B-4 in Attachment B). Any drawdown that may have occurred at these wells would be less than the post-deconvolution "noise" level of about 0.05 feet (0.6 inches).

The pumping well and observation well data from both of these tests were analyzed to estimate aquifer properties using the aquifer test software MLU (Hemker and Post, 2014; Hemker, 1999). For each test, the drawdown at pumping and observation wells was plotted and representative points on the drawdown curves were selected to define the drawdown input to MLU. A simple five-layer system was set-up in MLU, consistent with the layout of the numerical model. Layers 1-4 in the MLU analysis were each set to be 150 feet thick at HNWR-1, and 300 feet thick at Site-B, which reflects field observations of increasing aquifer thickness in the vicinity of Site B. Layer 5 at both sites was set to 300 feet.

The modeled fits to the observed drawdown data are shown in Figures B-11 and B-12. The estimated hydraulic conductivity (K) of the aquifer in this area is about 200 feet/day (ft/day), based on the results of the tests and the estimated thickness of the zone affected by the tests. These results were compared to the parameters in the numerical model, which is currently calibrated to a range of K-values from 30 – 200 ft/day, with typical K-values at 30 ft/day. Results from these aquifer tests represent a higher K than most areas of the Topock site on the California side of the Colorado River, where the typical K is about 30 ft/day. However, given the nature of the material encountered during drilling (sand and gravel), the estimated K from these tests corresponds well with the highest permeability materials found in the floodplain within the Topock project area on the California side, which have an estimated K of about 200 ft/day. The aquifer test area is within the large fluvial plain of the pre-dam era Colorado River, and the detailed drilling logs describe these clean fluvial deposits at a greater frequency and thickness than the fluvial deposits on the California side, which represents the thin western edge of the fluvial plain.

As a result of the test analysis, the transmissivity estimated for the aquifer is greater than that in the current flow model. When the flow model was last calibrated, there were no hydraulic data available in the area of these tests, and only regional indications of the aquifer thickness. The exploratory borehole at the HNWR-1 Site was drilled to a depth of 400 feet without encountering bedrock, which is double the assigned depth in the current model. Both the thickness and transmissivity of the fluvial deposits in this area will be increased in the model from the Topock Marina eastward to the edge of the regional model domain. The effects of these changes on the modeled site remedy effectiveness are expected to be minor, but there will be less regional influence of the freshwater pumping well(s) due to the higher permeability assigned to this area of the model.

Analysis of Water Quality Data. This section presents the results of field water quality measurement (Table 1) and laboratory analysis of the 12 groundwater samples collected from the HWNR-1 and Site B wells during constant-rate testing (Tables 2 through 9). In addition, these tables include the results from one sample collected from the HNWR-1 well on October 22, 2013, which was a "one-off" sample collected per the standard operating procedure for the Topock Groundwater Monitoring Program. Compared to the zone-specific samples collected from the exploratory boreholes, the samples collected during well testing are representative of a combined condition across the entire screened interval. HNWR-1 is effectively screened across the interval from 90.5 to 156 feet bgs and the Site B well is effectively screened across the interval from approximately 140 to 305 feet bgs.

Field Measurements. Field water quality measurements, including specific conductance, temperature, pH, oxidation-reduction potential, turbidity, and dissolved oxygen, were monitored during all testing activities (with the exception of dissolved oxygen during the HNWR-1 step test, which was not measured due to a

malfunctioning sensor). The water quality measurements collected during the step-rate and constant-rate tests were consistent at each well, which suggests that the water type entering the well screens does not vary significantly when each well is pumped across the range of flows utilized during step-rate testing, or throughout the duration of the constant-rate tests. The average specific conductance measurement collected during the constant-rate tests for HNWR-1 and Site B were 833 and 1,291 microSiemens per centimeter (μS/cm), respectively, which is consistent with the measurements collected from the corresponding depths in the respective exploratory boreholes. Oxidation-reduction potential and dissolved oxygen measurements also remained consistent during the respective tests, and are representative of the oxidizing water observed at these depths in the exploratory boreholes. Measurement of pH was consistent during both tests at approximately 7.9.

Temperature measurements were consistent throughout the constant-rate tests and consistent with measurements collected during the exploratory sampling. The average temperature during the constant-rate tests were approximately 37.6 and 35.8 degrees Celsius (approximately 99.7 and 96.4 degrees Fahrenheit) at HNWR-1 and Site B, respectively. The difference in temperature between the two wells could be attributed to the different pumps used for each test. The HNWR-1 test was conducted with a submersible pump, which has a motor (i.e., heat source) in the well, while the Site B test was conducted with a line-shaft pump that does not have a motor in the well. Comparing this temperature data to that from the groundwater on the California side of the Colorado River, the average temperature in the monitoring wells within the planned injection zone for the groundwater remedy is 29.6 degrees C, calculated among the means at each well. The overall range in temperature measurements is 23.2 to 34.7 degrees C. The density at 37.6 degrees, which was the average measurement at HNWR-1 (and the higher of the two sites), is approximately 0.003 kilograms per liter (kg/L) lower than that at 29.6 degrees, assuming equal TDS. This slight difference is not expected to cause a significant separation between injected and receiving waters, especially given the inherent heterogeneity of the alluvial aquifer. Also, the 8-degree difference in temperature is not significant enough for the warmer water to cause greater leaching of matrix minerals, since the solubility of the various oxides, hydroxides, and silicate minerals is virtually identical at these two temperatures.

Metals. The concentrations of metals detected in samples collected during constant-rate testing were consistent throughout each respective test. Detected concentrations of dissolved arsenic ranged from 14 to 16 and 17 to 18 μg/L in the HNWR-1 and Site B wells, respectively. These concentrations are consistent with those detected previously in HNWR-1. Detected concentrations of chromium ranged from 19 to 20 and 33 to 34 μg/L in the HNWR-1 and Site B wells, respectively. While the concentration in HNWR-1 is consistent with those detected previously in HNWR-1, the concentrations at Site B are higher. These higher concentrations likely occur because Site B is further north than HNWR-1, and therefore closer to the higher background concentrations of chromium that enter the basin from the Black Mountains, which are composed of ultra-mafic rocks that contain naturally occurring chromium and other metals.

Organics. Organic analyses included perchlorate, TPH, pesticides, PAHs, PCBs, and herbicides. All results for perchlorate, pesticides, PAHs, PCBs, and herbicides were non-detect. TPH as diesel and TPH as motor oil were detected at concentrations of 92 (estimated) and 130 μg/L, respectively in the sample collected from the Site B well immediately before the constant-rate test was ended. These TPH detections are believed to be associated with the pump tools and lubrication oil (a highly refined mineral oil) used along the shaft of the pump that operates within the well. These detections are not expected to persist.

Other Constituents. Other analyses including CLP inorganics, bromide, chloride, fluoride, nitrate/nitrite as nitrogen, soluble silica, sulfate, and total organic carbon were all consistent with the concentrations detected in samples from the exploratory boreholes of the corresponding depths. All results for gross alpha and gross beta were either non-detect or below the respective California maximum contaminant levels for drinking water, which are 15 and 50 picocuries per liter, respectively.

The results for stable isotopes of hydrogen and oxygen from samples collected during the constant-rate tests are consistent with the results discussed for the exploratory samples (see Section 3.1).

4.0 Recommendations for Design of the Groundwater Remedy

The following conclusions about the HNWR-1 and Site B wells are based on review of hydraulic and water quality data collected during this evaluation:

- HNWR-1 will currently supply enough water of sufficient quality to supply the groundwater remedy at the nominal design flow rate of 450 gpm, but not the maximum flow rate of 900 gpm. While the construction of the well was sufficient for its original intent (irrigation), it is not sufficient for long-term daily operation as reliable element of the groundwater remedy. Due to the design, construction, and condition of the well, as the well performance declines over time, the options for well maintenance are limited. Further, operational flexibility to lower the pump and generate more flow is limited by the diameter of the lower portion of the well.
- The Site B well will supply enough water to support the maximum designed remedy flow rate and the well construction allows optimal flexibility for operation (i.e., pump depth) and maintenance options; however, based on the current well construction and operation during well testing, the water quality is currently not optimal.
- Constant-rate extraction tests conducted for a duration of 72 hours at both HNWR-1 and the Site B well suggest that neither will substantially adversely affect the production rates of existing nearby wells (see EIR Mitigation Measure WATER-1, Addendum No. 1).

Based on these conclusions, the recommended path forward for establishing a reliable freshwater supply for the groundwater remedy includes:

1. **Depth-specific characterization of the Site B well.** While the current water quality from the Site B well is not optimal for the groundwater remedy (in and of itself), based on the analysis of well testing data, the well represents a viable freshwater source that can be used as a contingency option for the remedy water supply or to supplement another freshwater supply well[1]. It is recommended that depth-specific flow and water quality data be collected to support future decisions related to well operation for the groundwater remedy. For example, if depth-specific data suggests chromium is entering the well at a specific interval, the well operation or construction could potentially be modified to lower the chromium concentration in freshwater supplied by the well.
2. **Install a new well at the HNWR-1 Site.** A well that is designed and constructed for use as part of the groundwater remedy at the HNWR-1 Site could be expected to produce adequate quality and quantity of groundwater (i.e., the maximum designed remedy flow rate). A properly designed and constructed well would allow for the full range of well maintenance options for reliable, long-term operation. The new well would be installed by over-drilling/reaming the backfilled HNWR-1 Site exploratory borehole such that an additional borehole is not required.
3. **Design the infrastructure** that would be required to plumb and operate the Site B well as part of the groundwater remedy to support future contingency actions, as necessary. Conceptual pipeline routing and associated infrastructure is included as Attachment D. In addition, design infrastructure to service the new well at the HNWR-1 site.

The implementation of these steps should occur in parallel with the development of the 90 Percent Basis of Design Report so that the conclusions of the additional work can be included in the document.

[1] Additional wells that could be used to supplement Site B include well(s) at the HWNR-1 site, Topock-2, and Topock-3. At the request of the TRC during the March 19, 2014 TWG meeting, a water quality report from Southwest Water, Inc. is provided in Attachment C.

Notes:

uS/cm - MicroSiemens per centimeter

mg/L - Milligrams per liter

mV - Millivolts

°C - degrees Celsius

NTU - Nephelometric Turbidity Units

gpm - gallons per minute

Field water quality measurements collected using a field meter equipped with a flow cell (unless a bailer was used)

* Approximate water level measurements are expressed as feet below ground surface.

LEGEND

NOTE:
The lithology shown here was obtained from available driller's well logs and has not been independently verified by CH2M HILL with the exception of Site B and HNWR-1 exploratory borings to 400ft.

* In an effort to improve water quality the two deep screens in Topock-3 were isolated after installation. This well currently produces water from the shallow-most screen only.

Notice of Intent to Drill, Deepen, Replace or Modify a Well
(except a Non-Exempt Well in an Active Management Area)

$150 or $100 FEE

- Review instructions prior to completing form in black or blue ink.
- You must include with your Notice:
  - Check or money order in the amount of the appropriate filing fee.
  - For a well located within an AMA or INA, the fee is $150.00.
  - For a well not located within an AMA or INA, the fee is $100.00 if the well will be used solely for domestic purposes (see page 2 and instructions) and will have a pump with a maximum capacity of not more than 35 gallons per minute. Otherwise, the fee is $150.00.
- Authority for fee: A.R.S. § 45-596 and A.A.C. R12-15-104.

SECTION 1. COUNTY OR LOCAL HEALTH AUTHORITY APPROVAL (if applicable)

If water from the proposed well will be used for domestic purposes on a parcel of land of 5 or fewer acres, the applicable county or local health authority must endorse all items in Section 1 within one year before submission to the Department of Water Resources. You must also attach a site plan (pg. 3).

CHECK ONE

☐ County or Local Health Authority Recommends Approval (pursuant to A.R.S. § 45-596 (G) and (F))
- ☐ Field Inspection Performed
- ☐ Site Plan Review Only

☐ Insufficient Information to Make a Determination

Official County or Local Seal or Stamp

COUNTY OR LOCAL AUTHORITY NAME AND TITLE

TELEPHONE NUMBER | DATE | COUNTY OR LOCAL AUTHORITY SIGNATURE

SECTION 2. REGISTRY INFORMATION

Well Type

CHECK ONE

☐ Exempt
(Pump has a maximum capacity of not more than 35 gpm and water is not used for irrigation purposes inside an AMA.) *(See instructions.)*

☒ Non-Exempt
(Pump has a maximum capacity of more than 35 gpm and the well is located outside an AMA.) *(See instructions.)*

DESIGN PUMP CAPACITY
1,000 Gallons Per Minute

Proposed Action

CHECK ONE

SECTION 4.

Questions	Yes	No	If Yes:
1. Is the proposed well site within 100 feet of a septic tank system, sewer disposal area, landfill, hazardous materials or petroleum storage area or tank?		☒	You must also request a variance (A.A.C. R12-15-818).
2. Is there another well name or identification number associated with this well (e.g., Lot 35 Well, Smith Well, etc.)?		☒	PLEASE STATE
3. Is the proposed well a NEW well to be located within an Active Management Area? *(See instructions.)*		☒	Unless the well is a replacement well and the total number of operable exempt wells on the land is not increasing, you must also file a supplemental form A.R.S. § 45-454(C) & (D).
4. Is the proposed well the second exempt well on this parcel for the same use?		☒	If the proposed well is in an Active Management Area, you must also file a supplemental form A.R.S. § 45-454(I).

DATE CONSTRUCTION IS SCHEDULED TO BEGIN: October 2, 2013

SECTION 6. WATER / SITE INFORMATION

Principal Use of Water (CHECK ONE)	Other Uses of Water (CHECK ALL THAT APPLY)
☐ Irrigation	☒ Irrigation
☐ Commercial	☒ Commercial
☐ Domestic	☐ Domestic
☐ Municipal	☐ Municipal
☐ Industrial	☒ Industrial
☐ Stock	☐ Stock
☒ Remediation	☐ Remediation
☐ Dewatering	☐ Dewatering
☐ Other* (please specify):	☐ Other* (please specify):

NOTE: If this is a Notice of Intent to construct a new well that will be used for the purpose of withdrawing groundwater for transportation to an Active Management Area (AMA) pursuant to A.R.S. § 45-552, 45-553, 45-554 or 45-555(A), the authorization to drill the well issued in association with this Notice **shall not be considered the approval to transport groundwater to an AMA.** *(see instructions.)*

SECTION 7. PROPOSED WELL CONSTRUCTION DESIGN (attach separate sheet if needed)

Borehole: DEPTH FROM SURFACE FROM (feet)	Borehole: DEPTH FROM SURFACE TO (feet)	Borehole: BOREHOLE DIAMETER (inches)	Casing: DEPTH FROM SURFACE FROM (feet)	Casing: DEPTH FROM SURFACE TO (feet)	Casing: OUTER DIAMETER (inches)	Casing: MATERIAL TYPE (T): STEEL	PVC	ABS	IF OTHER TYPE, DESCRIBE	Casing: PERFORATION TYPE (T): BLANK OR NONE	WIRE WRAP	SHUTTER SCREEN	MILLS KNIFE	SLOTTED	IF OTHER TYPE, DESCRIBE	GROUTING MATERIAL
0	480	24	0	100	14.625	X*				X						Cement
			100	400	14.625	X					X					

* ADWR well construction standards require a surface seal consisting of a minimum of 20 feet of steel casing. Cement grout must be used to fill the annular space between the surface casing and the borehole. (A.A.C. R12-15-811(B))

The Department's issuance of an authorization to drill a well is not a determination of whether water withdrawn from the well is legally surface water or groundwater. The legal nature of the water withdrawn from the well may be the subject of court action in the future as part of a determination of surface water rights in your area. If there are court proceedings that could affect your well, you will be notified and be given the opportunity to participate. If you have questions regarding the legal nature of the water to be withdrawn from your proposed well, please consult with an experienced civil engineer, hydrologist or water rights attorney.

For the purposes of determining appropriate fees outside AMAs or INAs, "domestic purposes" is defined as "uses related to the supply, service and activities of households and private residences and includes the application of water to less than 2 acres of land to produce plants or parts of plants for sale or human consumption, or for use as feed for livestock, range livestock or poultry, as such terms are defined in A.R.S. § 3-1201."

SECTION 8. OPTIONAL BY PROPERTY OWNER AND WELL OWNER ONLY

☐ By checking this box, I hereby provide ADWR permission to enter the property for the purpose of taking water level measurements at this well. *(See instructions.)*

SECTION 9. WELL OWNER AND PROPERTY OWNER SIGNATURE

I state that this notice is filed in compliance with A.R.S. § 45-596 and is complete and correct to the best of my knowledge and belief.

TYPE OR PRINT NAME AND TITLE: Curt Russell (PG&E Topock Project Site Manager), Linda Miller (Refuge Manager)

SIGNATURE OF WELL OWNER: C Russell — DATE: 9-26-2013

SIGNATURE OF LANDOWNER, IF APPLICABLE (SEE INSTRUCTIONS): Refuge Manager — DATE: 09/26/13

- If this well will be a domestic well on 5 acres or less, please draw the following: (1) the boundaries of your property; (2) the proposed well location; (3) the locations of all septic tank systems and sewer systems on the property or within 100 feet of the well location, even if on neighboring properties; and (4) any permanent structures on the property that may aid in locating the well. If the parcel is vacant land or lacks a septic tank or sewer system, please indicate this.
- Indicate the distance between the proposed well location and any septic tank system or sewer system.

Notice of Intent to Drill, Deepen, Replace or Modify a Well

(except a Non-Exempt Well in an Active Management Area)

$150 or $100 FEE

- Review instructions prior to completing form in black or blue ink.
- You must include with your Notice:
  - Check or money order in the amount of the appropriate filing fee.
  - For a well located within an AMA or INA, the fee is $150.00.
  - For a well not located within an AMA or INA, the fee is $100.00 if the well will be used solely for domestic purposes (see page 2 and instructions) and will have a pump with a maximum capacity of not more than 35 gallons per minute. Otherwise, the fee is $150.00.
- Authority for fee: A.R.S. § 45-596 and A.A.C. R12-15-104.

SECTION 1. COUNTY OR LOCAL HEALTH AUTHORITY APPROVAL (if applicable)

If water from the proposed well will be used for domestic purposes on a parcel of land of 5 or fewer acres, the applicable county or local health authority must endorse all items in Section 1 within one year before submission to the Department of Water Resources. You must also attach a site plan (pg. 3).

CHECK ONE

☐ County or Local Health Authority Recommends Approval (pursuant to A.R.S. § 45-596 (G) and (F))
- ☐ Field Inspection Performed
- ☐ Site Plan Review Only

☐ Insufficient Information to Make a Determination

Official County or Local Seal or Stamp

COUNTY OR LOCAL AUTHORITY NAME AND TITLE

TELEPHONE NUMBER | DATE | COUNTY OR LOCAL AUTHORITY SIGNATURE

SECTION 2. REGISTRY INFORMATION

Well Type

CHECK ONE

☐ Exempt
(Pump has a maximum capacity of not more than 35 gpm and water is not used for irrigation purposes inside an AMA.)
(See instructions.)

☒ Non-Exempt
(Pump has a maximum capacity of more than 35 gpm and the well is located outside an AMA.)
(See instructions.)

DESIGN PUMP CAPACITY: 1,000 Gallons Per Minute

Proposed Action

CHECK ONE

☒ Drill New Well
☐ Deepen
☐ Replace
☐ Modify

If Deepening, Replacing or Modifying:

ORIGINAL WELL REGISTRATION NUMBER: 55 - NA

MAXIMUM CAPACITY OF ORIGINAL WELL: NA Gallons Per Minute

DISTANCE & DIRECTION FROM ORIGINAL WELL: NA Feet

Location of Well

WELL LOCATION ADDRESS (IF ANY): NA

COUNTY WHERE WELL IS LOCATED: Mohave

TOWNSHIP (N/S)	RANGE (E/W)	SECTION	160 ACRE	40 ACRE	10 ACRE

COUNTY ASSESSOR'S PARCEL ID NUMBER

BOOK	MAP	PARCEL	# OF ACRES
210	30	008	365

Place of Water Use *(Mandatory information, see instructions.)*

Is the groundwater basin where the well will be drilled the same as the place where the water will be used?	Yes	No
		☒

TOWNSHIP (N/S)	RANGE (E/W)	SECTION	160 ACRE	40 ACRE	10 ACRE
Used as part of the Topock Comp. Station's remediation.					

SECTION 3. OWNER INFORMATION

Well Owner

FULL NAME OF COMPANY, ORGANIZATION, OR INDIVIDUAL: Pacific Gas & Electric Company

MAILING ADDRESS: PG&E Topock Compressor Station PO Box 337

CITY / STATE / ZIP CODE: Needles CA 92363

CONTACT PERSON NAME AND TITLE: Curt Russell Topock Site Manager

TELEPHONE NUMBER: 760-791-5884 FAX: 760-326-5542

Landowner *(if different from Well Owner)*

FULL NAME OF COMPANY, GOVERNMENT AGENCY, OR INDIVIDUAL: Havasu National Wildlife Refuge

MAILING ADDRESS: 317 Mesquite Ave

CITY / STATE / ZIP CODE: Needles, CA 92363

CONTACT PERSON NAME AND TITLE: Linda L. Miller Refuge Manager

TELEPHONE NUMBER: 760-326-3853 x22 FAX: 760-326-5745

SECTION 4.

Questions	Yes	No	If Yes:
1. Is the proposed well site within 100 feet of a septic tank system, sewer disposal area, landfill, hazardous materials or petroleum storage area or tank?		☒	You must also request a variance (A.A.C. R12-15-818).
2. Is there another well name or identification number associated with this well (e.g., Lot 35 Well, Smith Well, etc.)?		☒	PLEASE STATE
3. Is the proposed well a NEW well to be located within an Active Management Area? *(See instructions.)*		☒	Unless the well is a replacement well and the total number of operable exempt wells on the land is not increasing, you must also file a supplemental form A.R.S. § 45-464(C) & (D).
4. Is the proposed well the second exempt well on this parcel for the same use?		☒	If the proposed well is in an Active Management Area, you must also file a supplemental form A.R.S. § 45-454(I).

			100	400	14.625	X					X					

* ADWR well construction standards require a surface seal consisting of a minimum of 20 feet of steel casing. Cement grout must be used to fill the annular space between the surface casing and the borehole. (A.A.C. R12-15-811(B))

The Department's issuance of an authorization to drill a well is not a determination of whether water withdrawn from the well is legally surface water or groundwater. The legal nature of the water withdrawn from the well may be the subject of court action in the future as part of a determination of surface water rights in your area. If there are court proceedings that could affect your well, you will be notified and be given the opportunity to participate. If you have questions regarding the legal nature of the water to be withdrawn from your proposed well, please consult with an experienced civil engineer, hydrologist or water rights attorney.

For the purpose of determining appropriate fees outside AMAs or INAs, "domestic purposes" is defined as "uses related to the supply, service and activities of households and private residences and includes the application of water to less than 2 acres of land to produce plants or parts of plants for sale or human consumption, or for use as feed for livestock, range livestock or poultry, as such terms are defined in A.R.S. § 3-1201."

SECTION 8. OPTIONAL BY PROPERTY OWNER AND WELL OWNER ONLY

☐ By checking this box, I hereby provide ADWR permission to enter the property for the purpose of taking water level measurements at this well. *(See instructions.)*

SECTION 9. WELL OWNER AND PROPERTY OWNER SIGNATURE

I state that this notice is filed in compliance with A.R.S. § 45-596 and is complete and correct to the best of my knowledge and belief.

TYPE OR PRINT NAME AND TITLE: Curt Russell (PG&E Topock Project Site Manager), Linda Miller (Refuge Manager)

SIGNATURE OF WELL OWNER: [signature] — DATE: 9-26-2013

SIGNATURE OF LANDOWNER, IF APPLICABLE (SEE INSTRUCTIONS): [signature] Refuge Manager — DATE: 09/26/13

- If this well will be a domestic well on 5 acres or less, please draw the following: (1) the boundaries of your property; (2) the proposed well location; (3) the locations of all septic tank systems and sewer systems on the property or within 100 feet of the well location, even if on neighboring properties; and (4) any permanent structures on the property that may aid in locating the well. If the parcel is vacant land or lacks a septic tank or sewer system, please indicate this.
- Indicate the distance between the proposed well location and any septic tank system or sewer system.

Variances & Exemptions {V&E} – State or EPA permission not to meet an MCL or a treatment technique under certain conditions.

Action Level – The concentration of a contaminant which, if exceeded, triggers treatment or other requirements which a water system must follow.

Treatment Technique {TT} – {Mandatory language} a treatment technique is a required process intended to reduce the level of a contaminant in drinking water.

Maximum Contaminant level – {Mandatory language} The "Maximum Allowed" {MCL} is the highest level of a contaminant that is allowed in drinking water. MCLs are set as close to the MCLGs as feasible using the best available treatment technology.

Maximum Contaminant Level Goal – {Mandatory language} The "Goal" {MCLG} is the level of a contaminant in drinking water below which there is no known or expected or expected risk to health. MCLGs allow for a margin of safety.

As you can see by the table, our system had no violations. We are proud that your drinking water meets or exceeds all Federal and State requirements. We have learned through our monitoring and testing that some constituents have been detected. The EPA has determined that your water **IS SAFE** at these levels.

All sources of drinking water are subject to potential contamination by substances that are naturally occurring or man made. These substances can be microbes, inorganic or organic chemicals and radioactive substances. All drinking water, including bottled water, may reasonably be expected to contain at least a small of some contaminants. The presents of contaminates does not necessarily indicate that the water poses a health risk. More information about contaminants and potential health effects can be obtained by calling the Environmental Protection Agency's Safe Drinking Water Hotline at 1-800-426-4791

MCLs are set very stringent levels. To understand the possible health effects described for many regulated constituents, a person would have to drink 2 liters of water every day at the MCL level for a lifetime to have a one-in-a-million chance of having the described health effect.

Some people may be more vulnerable to contaminants in drinking water than the general population. Immuno-compromised persons such as persons with cancer undergoing chemotherapy, persons who have undergone organ transplants, people with HIV?AIDS or other immune system disorders, some elderly and infants can particularly at risk from infections. These people should seek advice about drinking water from their health providers. EPA/CDC guidelines on appropriate means to lessen the risk of infection by cryptosporidium and other microbiological contaminants are available from the Safe Water Hotline 1-800-426-4791.

We at SOUTHWEST WATER INC. work hard to provide top quality water to every tap. We ask that all our customers help us protect our water sources, which are the heart of our community, our way of life and our children's future. Please call our office if you have any questions: 928-219-9358.

SOUTHWEST WATER INC.

ANNUAL CONSUMER CONFIDENCE REPORT

08-033 **Date: July 2011**

Reporting Period For 2010

SOUTHWEST WATER INC. is pleased to present to you this year's Annual Quality Water Report. This report is designed to inform you about the quality of water and services we deliver to you every day. Our constant goal is to provide you with a safe end dependable supply of drinking water. We want you to understand the efforts we make to continually improve the water treatment process and protect our water resources. We are committed to ensuring the quality of your water. Our water source is in the Warm Springs Aquifer.

SOUTHWEST WATER INC. routinely monitors for constituents in your drinking water according to Federal and State laws. As water travels over the land or underground, it can pick up substances or contaminates such as microbes, inorganic and organic chemicals and radioactive substances. All drinking water, including bottled drinking water may be reasonably expected to contain at least small amounts of some constituents. It is very important to remember that the presence of these constituents does not necessarily pose a health risk.

In this table you will find many terms and abbreviations you might not be familiar with. To help you better understand these terms we have provided the following definitions:

Non-detects {ND} - Laboratory analysis indicates that constituent is not present.

Parts per million {ppm} or Milligrams per liter – {mg/l} – One part per million corresponds to one minute in two years or a single penny in $10,000.

Parts per billion {ppb} or Micrograms per liter – One part per billion corresponds to one minute in 2,000 years, or a single penny $10,000,000.

Parts per trillion {ppq} or nanograms per liter {nanograms/l} – One part per quadrillion corresponds to one minute in 2,000,000 years, or one penny in $10,000,000,000.

Parts per quadrillion {ppq} or pictograms per liter {pictogram/l} – one part per quadrillion corresponds to one minute in 2,000,00,000 years or one penny in $10,000,000,000,000.

Picocuries per liter {pCiL} – Picocuries per liter is a measure of the radioactivity in water.

Millirems per year {mrem/yr} – Measure of radiation absorbed by the body.

Million fibers per liter {MFL} – million fibers per liter is a measure of the asbestos fibers that are longer than 10 micrometers.

DWAR 2IN: Revised 7/2009

Microbiological Contaminants

Contaminant	MCL	MCLG	Unit	Result	Violation (Yes or No)	Sample Date	Likely Source of Contamination
Total Coliform Bacteria for Systems that collects>40 samples per month	No more than 5% of monthly samples can be positive	0	Absent or Present	a	N	2011	Naturally present in the environment
Total Coliform Bacteria for Systems that collects<40 samples per month	No more than 1 positive monthly sample	0	Absent or Present	a	N	2011	Naturally present in the environment
Fecal coliform and E. Coli	A routine sample & a repeat sample are total coliform positive, & one is also fecal coliform or *E. coli positive*	0	Absent or Present	a	N	2011	Human and animal fecal waste

Lead and Copper

Contaminant	AL	ALG	Units	90th Percentile	Number of Sites over AL	Violation (Yes or No)	Sample Date/Year	
Copper	1.3	0	ppm	.018	5	N	07-11	
Lead	15	0	ppb	0184	5	N	07-11	

Inorganic Contaminants

Contaminate	MCL	UN	Units	Level Detected/ Range	Violation	Sample Date	
Nitrate (as Nitrogen) Poe#1	10	10	ppm	2.2	N	04-11	Runoff from fertilizer use; leaching from septic tanks, sewage; erosion of natural deposits

Secondary Contaminants

Secondary standards are non-enforceable guidelines for contaminants that may cause cosmetic effects or aesthetic effects in drinking water. EPA recommends these standards but does not require water systems to comply.

Contaminant	Secondary Standard	MCLG	Units	Level detected/ Range	Violation		

Violations

The following violations were received by our water system or were ongoing in the calendar year 2011

Type/Description	Compliance Period
NONE	

Please contact **Victor Hewlett** at SouthWest Water inc. 928.219.9358 to learn more about what you can do to help protect your drinking water sources, any questions about the annual drinking water quality report, to learn more about our system, or to attend scheduled public meetings. We want you, our valued customers, to be informed about the services we provide and the quality water we deliver to you every day.

Health Effects Information About the Above Tables

Nitrate in drinking water at levels above 10 ppm is a health risk for infants of than six months of age. High nitrate levels in drinking water can cause blue baby syndrome. Nitrate levels may rise quickly for short periods-of-time because of rainfall or agricultural activity. If you are caring for an infant, and detected nitrate levels are above 5 ppm, you should ask advice from your health care provider.

Addendum to the Summary of Findings Associated with the Evaluation of Alternative Freshwater Sources in the Topock Remediation Project Area, Pacific Gas and Electric Company, Topock Compressor Station, Needles, California

PREPARED FOR: Pacific Gas and Electric Company

PREPARED BY: CH2M HILL

DATE: September 8, 2014

Summary

This technical memorandum summarizes additional activities conducted from May to July 2014 (referred to herein as Phase 2) and associated findings for the evaluation of alterative freshwater sources as defined in the *Final Implementation Plan for Evaluation of Alternative Freshwater Sources in the Topock Remediation Project Areas, Pacific Gas and Electric Company, Topock Compressor Station, Needles, California* (Work Plan) (CH2M HILL, 2013b). Initial activities conducted from October 2013 to February 2014 (referred to herein as Phase 1) and associated findings are summarized in the technical memorandum titled *Summary of Findings Associated with the Evaluation of Alternative Freshwater Sources in the Topock Remediation Project Area, Pacific Gas and Electric Company, Topock Compressor Station, Needles, California (referred to herein as the Phase 1 Report)* (CH2M HILL, 2014). Phase 2 activities were conducted in accordance with the April 4, 2014 joint direction letter from United States Department of the Interior (DOI) and California Department of Toxic Substances Control (DTSC) regarding the freshwater well location for the Topock groundwater remedy (DOI, 2014).

The following primary activities were conducted during the implementation of Phase 2 at the two freshwater source evaluation locations (Site B and the HNWR-1 Site, which includes the area of the existing Havasu National Wildlife Refuge (HNWR) well HNWR-1 and new well HNWR-1A) (see Figure 1):

- Performed flow profile testing and associated zone-specific groundwater sampling at the Site B well.
- Constructed and developed a new well at the HNWR-1 Site using the exploratory borehole installed during Phase 1 as a pilot hole. This new well is referred to as HNWR-1A.
- Following well development, a step-rate extraction test was conducted at the new HNWR-1A well to evaluate well performance.
- Irrigated water that was pumped during Site B well flow profile testing and HNWR-1A well development and well testing activities at the HNWR future re-vegetation plot, as indicated in the Work Plan (CH2M HILL, 2013b).
- Conducted pre-construction surveys for biological, paleontological, and cultural resources (the post-construction biological survey is complete and the associated report is in progress).
- Conducted monitoring for biological, paleontological, and cultural resources during all field work.

In addition to discussion during routine project meetings, updates on Phase 2 field work were provided during the June and July, 2014 Technical Working Group (TWG) meetings.

The following conclusions about the freshwater supply for the groundwater remedy are based on review of hydraulic and water quality data collected during both phases of this evaluation:

- **HNWR-1 water quality and well performance.** Based on data collected during Phase 1, HNWR-1 will currently supply enough water of sufficient quality to supply the groundwater remedy at the nominal design flow rate of 450 gallons per minute (gpm), but not the maximum flow rate of 900 gpm. While the construction of the well was sufficient for its original intent (irrigation), it is not sufficient for long-term daily operation as a reliable element of the groundwater remedy. Due to the design and construction of the well the options for aggressive and effective well maintenance are limited. Further, operational flexibility to lower the pump and generate more flow is limited by the smaller diameter of the lower portion of the well.
- **Site B water quality and well performance.** Based on data collected during Phase 1, the Site B well will supply enough water to support the maximum designed remedy flow rate and the well construction allows optimal flexibility for operation (i.e., pump depth) and maintenance options; however, based on current well construction and operation during testing, the water quality is currently not optimal. The Site B well flow profile testing and associated zone-specific groundwater sampling conducted during Phase 2 suggests that the well currently has little water quality stratification; therefore, it is unlikely that modification to the well construction will result in a change in the water quality produced from the well.
- **HNWR-1A water quality and well performance.** Like nearby well HNWR-1, water quality from the HNWR-1A well is adequate to supply the groundwater remedy; however, unlike HNWR-1, the quantity of water that the well will produce exceeds the maximum estimated demand for remedy operation. Further, the well construction is sufficient for long-term daily operation as a reliable element of the groundwater remedy and is suitable for a range of well maintenance options, as determined necessary during remedy operation.
- **EIR Mitigation Measures WATER-1.** 72-hour constant-rate extraction tests conducted during Phase 1 at both HNWR-1 and the Site B well suggest that neither will substantially adversely affect the production rates of existing nearby wells (see EIR Mitigation Measure WATER-1, Addendum No. 1). Data collected during these tests were used to update the groundwater flow model for the Arizona side of the Colorado River. The updated model was re-run to simulate drawdown in nearby well Topock-2 with the operation of HNWR-1A, which has a slightly different construction than HNWR-1, at the nominal flow design flow rate of 450 gpm. This simulated pumping in HNWR-1A results in an additional 0.1 feet of drawdown compared to HNWR-1; therefore, pumping at HNWR-1A also will not substantially adversely affect the production rates of existing nearby wells.

Based on this information the recommended path forward for establishing a freshwater supply for the groundwater remedy that provides the maximum flexibility and reliability includes:

1. Utilization of HNWR-1A as the primary freshwater supply for the groundwater remedy.
2. Designing the infrastructure required to plumb and operate the HNWR-1 well as a secondary freshwater supply.
3. Designing the infrastructure required to plumb and operate the Site B well as a contingency freshwater supply. While the Site B well will provide an adequate quantity of water, blending with another supply will likely be required to lower the naturally occurring hexavalent chromium concentration below 32 μg/L.

1.0 Introduction

Pacific Gas and Electric Company (PG&E) is implementing the selected groundwater remedy for chromium in groundwater at the PG&E Topock Compressor Station (TCS, or the Compressor Station) in San Bernardino County, California. Remedial activities at the Topock site are being performed in conformance with the requirements of the Resource Conservation and Recovery Act (RCRA) Corrective Action pursuant to a Corrective Action Consent Agreement (CACA) entered into by PG&E and the California Department of Toxic

Substances Control (DTSC) in 1996, as well as the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) pursuant to pursuant to a Remedial Design/Remedial Action Consent Decree between the United States and PG&E, entered by the United States District Court for the Central District of California on November 21, 2013.

As an element of the final groundwater remedy design, freshwater sources, including groundwater supply wells and the Colorado River, have been considered for use during remedy operation. The average and maximum volume of freshwater required for remedy operation is estimated to be 450 and 900 gpm, respectively, based on groundwater modeling. In the *Basis of Design Report/Intermediate (60%) Design for the Final Groundwater Remedy* (CH2M HILL, 2013b), PG&E presented a plan to obtain freshwater from a well on HNWR—well HNWR-1.

This technical memorandum summarizes the activities conducted and associated findings for Phase 2 of the evaluation of alterative freshwater sources as defined in the Work Plan (CH2M HILL, 2013b).

1.1 Approvals and Authorizations

Phase 2 of the Topock Alternative Freshwater Source Evaluation was executed in conformance with the following approvals and authorizations:

- DTSC acceptance of the Work Plan (DTSC, 2013b) and approval for implementation subject to conditions set forth in the letter (DTSC, 2012), which included Mitigation Measures adopted by the certified Final Environmental Impact Report (DTSC, 2011) as specified in the EIR Addendum (No. 1) for the Alternative Freshwater Source Evaluation.
- U.S. Department of Interior [DOI], Bureau of Land Management [BLM], U.S. Fish and Wildlife Service [USFWS], and Bureau of Reclamation [Reclamation] acceptance of the Work Plan (DTSC, 2013b) and approval for implementation subject to the conditions set forth in the letter (DOI, 2013).
- HNWR acceptance of the Work Plan (CH2M HILL, 2013b) and approval for implementation subject to the conditions set forth in the email to Yvonne Meeks of PG&E (HNWR, 2012).
- The April 4, 2014 joint direction letter from DOI and DTSC regarding the freshwater well location for the Topock groundwater remedy (DOI, 2014).

1.2 Coordination with Agencies and Tribes

Immediately prior to conducting any ground disturbing activities, a project initiation tailboard meeting was held at the HNWR-1 Site on May 30, 2014. During this meeting, representatives from PG&E and Tribes discussed the details of the planned fieldwork, biological, paleontological, cultural, and historical sensitivities associated with the project area, and conducted a walk of the fieldwork site. During work, in addition to discussion during routine project meetings, updates on Phase 2 field work were provided during the June and July, 2014 Technical Working Group (TWG) meetings. Tribal monitors participated throughout the fieldwork and were provided with routine field schedule updates.

1.3 Technical Memorandum Organization

The remainder of this technical memorandum is organized in the following manner:

- **Section 2.0** summarizes the field activities conducted throughout the evaluation.
- **Section 3.0** presents the analysis of the data collected during Phase 2 of the evaluation, including the results of laboratory analysis of groundwater samples, and analysis of well testing data.
- **Section 4.0** summarizes the PG&E recommended path forward for establishing a freshwater supply for the groundwater remedy.
- **Section 5.0** provides a list of works cited in this technical memorandum.

2.0 Summary of Field Activities

Primary field activities conducted during Phase 2 included well construction, development, and testing of the HNWR-1A well, and testing of the Site B well. All project activities were performed under the supervision of both a California and Arizona Professional Geologist. This section describes the details of each element of work conducted.

2.1 Site Access, Preparation, Compliance Monitoring, and Security

An onsite biologist conducted a pre-construction survey before work began. Biological monitoring was conducted daily throughout fieldwork by a field contact representative (FCR) that was trained by the biologist prior to the beginning of work. The post-construction survey for the site was completed on July 24, 2014. The pre- and post-construction survey data will be used to assess and document compliance with the Programmatic Biological Assessment (PBA) (CH2M HILL, 2007). The results of the surveys will be provided in a biological resources completion report, which is scheduled for submittal to BLM and the Havasu National Wildlife Refuge (HNWR) 60 days after the completion of fieldwork.

An onsite archaeologist/paleontologist conducted a pre-construction survey before work began for cultural and paleontological resources. All site activities were monitored daily by an onsite archaeologist. Tribal monitors, who were invited to observe all site activities, monitored many of the activities. The paleontologist was on-call throughout the fieldwork, but was not contacted by the field team, as paleontological resources were not observed during drilling.

Access for HNWR-1A drilling, Site B well flow profile testing and irrigation equipment deployment was accomplished using previous routes developed during work conducted in 2013 (Phase 1) that are identified in the Work Plan (CH2M HILL, 2013b). The existing land surfaces at the work sites were not graded or changed from the conditions established during Phase 1. No listed species or nesting birds were observed during the pre-activity or post-activity surveys.

Existing temporary fencing was utilized to control site access. Onsite security was utilized to monitor the work areas during non-working hours. No incidences of unauthorized site access were detected during work.

The HNWR-1A drilling location was initially surveyed for underground utilities prior to Phase 1 field work in 2013. The Arizona Blue Stake mark-and-locate program was utilized at HNWR-1A immediately prior to mobilization and drilling for Phase 2.

Project activities were conducted in compliance with the items identified in Attachment B of the Work Plan (CH2M HILL, 2013a), which includes compliance with Applicable and Relevant or Appropriate Requirements, the PBA (CH2M HILL, 2007), the Programmatic Agreement (BLM, 2010), and the Cultural and Historic Properties Management Plan (BLM, 2012). Compliance monitoring activities associated with the EIR Addendum No. 1 Mitigation Measures Reporting Program (MMRP), which is also included in Attachment B to the Work Plan (CH2M HILL, 2013a), were conducted continuously during fieldwork associated with the Work Plan (CH2M HILL, 2013b) and are documented in the quarterly compliance reports, which are available on the DTSC website for the Topock Project Site.

2.2 Previous Work at the HNWR-1 Site

During October 2013, one 8-inch diameter exploratory borehole was installed to a depth of 400 feet below ground surface (bgs) at location HNWR-1A (previously referred to as the “HNWR-1 Site exploratory borehole”) to facilitate collection of lithologic and zone-specific groundwater samples. The exploratory borehole was drilled using the dual-rotary method (using a Foremost DR-24 drill rig), which rotates both an outer primary casing and the drill string (attached to the drill bit), independently as described in the Phase 1 Report. Drill cuttings collected during HNWR-1A exploratory drilling were logged in accordance with the methods and procedures identified in the Work Plan (CH2M HILL, 2013b). The lithologic log for HNWR-1A is included in Attachment A. Zone-specific groundwater samples were collected from the HNWR-1A

exploratory borehole approximately every 50 feet to assess changes in water quality with depth. Groundwater quality field measurements and laboratory results from the zone-specific sampling are included in Tables 1 through 9.

Data from the HNWR-1A exploratory borehole indicated that the unconsolidated aquifer is comprised largely of well-graded gravels and sand. Zone-specific water quality samples indicated a stratified aquifer with higher specific conductance (saltier) water occurring deeper in the borehole, and more fresh (less salty) water occurring in the shallower interval. The transition from fresh (less salty) water to saltier water is between 250 and 300 feet bgs, where the specific conductance of zone-specific groundwater samples increased from approximately 1,405 □S/cm to 26,300 □S/cm. The HNWR-1 Site is located within the large fluvial plain of the pre-dam era Colorado River, and the detailed logs describe these clean fluvial deposits at a greater frequency and thickness than the fluvial deposits on the California side of the River, which represents the thin western edge of the fluvial plain.

After HNWR-1A exploratory drilling and sampling was complete, the exploratory casing was removed and the borehole was decommissioned on February 2, 2014 in accordance with the Work Plan (CH2M HILL, 2013b) as discussed in the Phase 1 Report (CH2M HILL, 2014a). The borehole was decommissioned by backfilling from total depth (400 feet) to 22 feet bgs with pea gravel. The interval from 2 to 22 feet bgs was sealed using cement bentonite grout (installed via tremie) and the upper most 2 feet was backfilled with granular material from the existing site area (i.e., drill cuttings from the borehole and surface soil adjacent to the borehole).

Hydraulic testing was performed at the HNWR-1 well (prior to the installation of HNWR-1A, which is now located approximately 60 feet from HNWR-1A) to assess well performance and estimate aquifer properties. A step-rate extraction test was conducted at the HNWR-1 well on October 16, 2013, and a 72-hour constant-rate extraction test was conducted from February 11 to 14, 2014. The step-rate test consisted of six 90-minute steps with the following average flow rates: 278 gpm, 382 gpm, 472 gpm, 557 gpm, 658 gpm, and 767 gpm. A seventh step was attempted at 875 gpm (maximum pump flow) but the pump began to cavitate after approximately 30 minutes, indicating that water level drawdown in the well had dropped below the minimum operating head required above the pump. Based on analysis of the step-rate extraction test, a flow of 700 gpm was chosen for the constant-rate test. HNWR-1 is located approximately 750 feet from the Topock-2 and -3 supply wells, which are operated by Southwest Water Company to provide freshwater to the Topock Compressor Station, Topock-66 restaurant, and nearby residences. Prior to the beginning of the HNWR-1 constant-rate test, project staff coordinated with the Southwest Water Company to fill available storage on the compressor station and for the residences/Topock-66 restaurant so that well operation could be minimized during the HNWR-1 testing period. As summarized in the Phase 1 report (CH2M HILL, 2014), the results of the HNWR-1 constant-rate extraction test suggests that operation of the HNWR-1 well will not substantially adversely affect the production rate of existing nearby wells (see EIR Mitigation Measure WATER-1, Addendum No. 1).

2.3 HNWR-1A Well Drilling, Construction and Development

Following joint direction received from DTSC and DOI (DOI, 2014) a drill rig and field crew re-mobilized to the site and the existing HNWR-1A exploratory boring was reamed/over drilled for the installation of a new well. Well design was based on evaluation of lithologic data from recovered drill cuttings, and the results of field measurement and laboratory analysis of zone-specific groundwater samples collected during Phase 1. Borehole drilling, well construction, and well development activities were conducted from May 30, 2014 to June 29, 2014. The materials and methods used for constructing and developing the HNWR-1A well are presented in this section. Although drilling and well installation activities conducted as part of the Work Plan (CH2M HILL, 2013b) are exempt from the requirement to obtain well installation permits from the ADWR pursuant to the CERCLA Section 121(e)(1) permitting exemption, a notice of intent (NOI) to install a well at the HNWR-1 Site previously existed since it had only been used for the exploratory borehole and was still

valid for a well drilled in the same borehole (see Attachment A). The substantive requirements associated with the approved NOI were followed.

The HNWR-1A well was drilled and constructed using the dual-rotary drilling method (using a Foremost DR-24 drill rig) as follows:

1. **Drilled the borehole for well construction.** Once the drill rig was set up over the existing exploratory borehole, a 20-inch-diameter (nominal) borehole was drilled to a total depth of 205 feet bgs.
2. **Installed the well casing and annular materials.** After the 20-inch diameter borehole was drilled to total depth, the well casing was installed within the primary drill casing. The well casing and screen are 14-inch diameter, 316L stainless steel (all joints were welded). Well screen is wire wrapped with 0.090-inch open spacing between wires. Filter pack material was installed through the primary casing, and seal materials were installed via tremie within the primary drill casing, which was removed from the borehole in stages as annular materials were installed around the well casing. Filter pack annular material is composed of Premier Silica 6x9 gradation sand. The well was constructed with the following casing and screen intervals:
   - Ground surface to 63 feet bgs – blank cased with the annular space sealed from 51 feet bgs to the ground surface with cement bentonite grout.
   - 63 to 133 feet bgs – screened with filter sand in the annular space.
   - 133 to 154 feet bgs – blank cased with an intermediate annular seal composed of hydrated bentonite pellets from 136 to 146 feet bgs. This section could be used as the pump chamber or could provide a place to set a packer in the event the lower screened section needed to be isolated to exclude poorer quality water.
   - 154 to 194 feet bgs – screened with filter sand in the annular space.
   - 194 to 204 feet bgs – blank cased with a welded plate on the bottom and filter sand in the annular space (this section comprises the sump).

   Figure 2 presents an update of the conceptual geologic cross-section that was included in the Work Plan (CH2M HILL, 2013b). The updated cross-section reflects additional data collected during both Phase 1 and Phase 2, including well construction and water quality data for HNWR-1A.
3. **Completed the wellhead.** The stainless steel well casing was completed approximately 5 feet above ground surface, and sealed with stainless steel cap. Like the Site B well that was installed during Phase 1, the HNWR-1A well will be finished with a flange welded to the well casing and sealed with a blank flange plate (bolted with gasket) so that it can be easily accessed and plumbed into the groundwater remedy pipeline. A mild steel protective casing will be installed around and above the production casing with a hinged cap that is secured with a padlock, which is similar to other wells associated with the Topock Remediation Project. These well head modifications will be completed in September 2014.

A well construction diagram summarizing this information is provided in Attachment A.

Well development was initially conducted using the drill rig with a dual-swab airlift tool. This high-energy development method used compressed air to extract groundwater from the well. The dual-swab tool was made of steel pipe with openings along a 5-foot interval and rubber gaskets (swabs) at the top and bottom of the 5-foot section to focus the pumping energy along specific intervals of well screen. Following airlift development, a submersible pump was installed in the well and used to surge the well at multiple flow rates. Sand production and water quality measurements (e.g., temperature, specific conductance, pH, oxidation-reduction potential, and dissolved oxygen) were monitored on the effluent water at the surface during well development. Approximately 360,000 gallons were removed during initial airlift development, and 1,570,600 gallons were removed during pump development.

Following construction, development, and testing (see Section 2.5), a video survey and a gyroscope survey were conducted in the well to verify the as-built well details and condition on July 9, 2014. The video survey confirmed the well construction details outlined above and that the well screen, casing, and welded joints were in good condition (a summary of the video survey is provided in Attachment A). The gyroscope survey was used to verify that the well casing was plumb and straight.

2.5 HNWR-1A Step-Rate Discharge Testing

On June 24, 2014, a 12-hour step-rate discharge test was conducted at the HNWR-1A well to assess well performance and to estimate the upper operational flow that could be sustained. The test was conducted using a submersible electric pump installed with the intake at approximately 145 feet bgs. The step-rate test consisted of six 120-minute steps with the following average flow rates: 481 gpm, 704 gpm, 881 gpm, 1,095 gpm, 1,298 gpm, and 1,483 gpm. A plot of the drawdown data collected during the HNWR-1A step-rate test is provided in Figure B-1 in Attachment B.

Effluent water quality measurements (e.g., temperature, specific conductance, pH, oxidation-reduction potential, and dissolved oxygen) were monitored during the test. Water quality samples for laboratory analysis were collected from the pump effluent during each step to qualify changes over pumping rates. The samples collected at each step were analyzed for Title 22 metals, hexavalent chromium, total chromium, silica, fluoride, and nitrate. A sample was collected during the third step (881 gpm) and was analyzed for a longer list of analytes including CAM 17 metals, deuterium, oxygen 18, perchlorate, petroleum hydrocarbons, pesticides, polyaromatic hydrocarbons, polychlorinated biphenyls, herbicides, chloride, sulfate, silica, nitrate, nitrite, fluoride, bromide, phosphate, general minerals, total organic carbon, pH, and gross alpha and beta. The third step was selected for a longer list of analytes because the flow rate was closest to the maximum design flow rate of 900 gpm.

Pressure transducers were utilized in HNWR-1 and Site B to observe potential effects of HNWR-1A pumping during the step-rate test. All groundwater discharged during the test (715,900 gallons) was surface irrigated to the area designated in the Work Plan (CH2M HILL, 2013b) (see Section 2.7) and was managed with zero run-off from the designated irrigation area.

2.6 Site B Well Flow Profile Testing

Dynamic (i.e., the pumping head condition) flow profile testing and associated water quality profile sampling were conducted to assess flow contribution and associated water quality concentrations under operational conditions for all Site B well screened intervals. Specifically, the flow contribution of each 10-ft section of well screen was evaluated and zone-specific groundwater samples were collected at 8 points along the well screen (plus one sample of pumping effluent at the well head) to evaluate the contribution of arsenic, hexavalent chromium, fluoride, and TDS concentrations to the well (a longer list of metals was analyzed, but the analysis focused on these four). Fieldwork related to flow profile testing at the Site B well was completed over two days with the dynamic flow profile test conducted on June 11, 2014 and zone-specific groundwater sampling completed on June 12, 2014. Prior to the initiation of data collection for the flow profile and water quality sampling, the well was pumped at a constant flow rate of 986 gpm for approximately 24 hours to establish a steady-state flow condition.

Dynamic Flow Profile Testing. Flow contribution in the Site B well was measured by injecting dye at 13 discrete depths from 140 to 310 ft bgs while pumping at 986 gpm. The dynamic flow profile was performed using the USGS Tracer Pulse Dynamic Flow Profile method (USGS white papers are provided in Attachment B) to measure flow contribution along the length of the well, which is accomplished by injecting low concentrations of biodegradable, food grade dye at different depths in the well during pumping. The dynamic flow profile was evaluated by maintaining a constant flow rate of 986 gpm with the pump installed in the cased section of the well above all screened intervals during the flow profile testing activities. The flow profile is calculated based on dye travel time from the injection point within the well to the wellhead at ground surface where the dye is detected in the discharge water. Results from flow profile testing were used

to determine the depths of the groundwater samples that would be used to evaluate the water quality profile.

Water Quality Sampling. While maintaining a constant flow rate of 986 gpm at Site B well, water quality samples for laboratory analysis were collected on June 12, 2014 at the following nine depths: 0 (pump effluent), 140, 165, 175, 190, 205, 215, 235, and 255 ft bgs.

The samples collected at each depth were analyzed for Title 22 metals, hexavalent chromium, fluoride, and TDS; however, the analysis of the flow profile testing data focused on total chromium, hexavalent chromium, fluoride, and TDS. Effluent water quality measurements (e.g., temperature, specific conductance, pH and oxidation-reduction potential) were monitored in the field during the water quality sampling.

2.7 Management of Material Generated During Evaluation

Three types of materials were generated during fieldwork: drill cuttings, purged groundwater, and trash, all of which were managed in accordance with the Work Plan (CH2M HILL, 2013b). Drill cuttings and purged groundwater were managed in accordance with site-specific and regulatory practice for groundwater supply well drilling. Because this work was conducted as part of a CERCLA response action, implementation plan activities conducted onsite were covered under the permit exemption codified in Section 121(e)(1) of CERCLA. While the permit exemption applies to the administrative or procedural elements (e.g., preparing and submitting permit applications and obtaining permits), the substantive requirements of the applicable laws remain. Groundwater discharge and drill cuttings were managed in compliance with the substantive requirements of Aquifer Protection General Permit 1.04, as authorized by Arizona Administrative Code Section R18-9-B301(D).

Drill cuttings were diverted from the cuttings return pipe on the rig using a cyclone that was staged over the top of a tank. From the tank all drill cuttings were spread to the ground surface adjacent to the borehole. Chemical additives were not used during drilling, therefore cuttings sampling was not necessary to determine suitability for discharge to the ground surface. Drill cuttings were not discharged to any jurisdictional areas. Clay was recovered in the drill cuttings from the borehole. In accordance with the Work Plan (CH2M HILL, 2013b), the clay material was gathered and separated from the other drill cuttings for storage on dye-free cotton muslin fabric and labeled. The material was recovered from the cuttings bin as many small clay balls, which were subsequently aggregated into a larger ball that was approximately the size of a medium beach ball. The material was securely stored at the work site, and the agencies and Tribes were informed of the clay. The project archaeologist, in coordination with the Tribes, subsequently managed the material.

Purged groundwater was generated during drilling, well development, and well testing at HNWR-1A, and flow profile testing at the Site B well. Water generated during drilling (see Section 2.3) was discharged to the ground surface in the same area as the drill cuttings. Water was generated at a higher rate during development well testing and flow profile testing and was surface irrigated to the area designated in the Work Plan (CH2M HILL, 2013b). The water was pumped through a temporary, aboveground conveyance pipeline to as many as 12 sprinklers in the irrigation area (see Figure 3). During key development activities, discharge was irrigated directly to the ground without the use of a sprinkler to avoid discharge pressure limitations associated with the sprinkler equipment; however, all discharge activities were conducted in a manner that did not promote scouring or erosion of the irrigation area. A total volume of approximately 5.26 million gallons was discharged to the irrigation area during development and testing at HNWR-1A and flow profile testing at Site B. Purged groundwater was neither discharged nor allowed to run-off to jurisdictional areas, the Colorado River, nor Arizona County Highway 10.

Incidental trash was removed from the work area daily and was transferred to a standard trash bin at the TCS for offsite disposal.

3.0 Results of the Evaluation

This section presents the analysis of data collected during the activities detailed in Section 2. Section 4 discusses the integration of all available data from this evaluation, and associated recommendations for the recommended path forward in establishing a freshwater supply for the groundwater remedy.

3.1 Aquifer Testing Data

The step-rate extraction test at HNWR-1A was conducted for 12 hours. Drawdown at HNWR-1A is shown in Figure B-1 in Attachment B. The HNWR-1A step-rate test was conducted at a maximum average flow rate of 1,483 gpm, which maintained approximately 40 feet of water level drawdown in the well.

Pumping at HNWR-1A during the step-rate extraction test produced measurable drawdown in the HNWR-1 well (approximately 8 feet) but there was no apparent drawdown at the Site B well. The water levels and pumping rates/times were not monitored in the Topock-2, Topock-3 or Marina wells during the HNWR-1A step-rate extraction test as they were during the HNWR-1 constant rate extraction test (conducted during Phase 1).

Analysis of Water Quality Data. This section presents the results of field water quality measurement (Table 1) and laboratory analysis of the six groundwater samples collected during the HWNR-1A step-rate test (Tables 2 through 9) on June 24, 2014. The samples collected during each step are representative of a combined condition across the entire screened interval for each flow rate.

Field Measurements. Field water quality measurements, including specific conductance, temperature, pH, oxidation-reduction potential, turbidity, and dissolved oxygen, were monitored during testing activities. The water quality measurements collected during the step-rate test were consistent with the HNWR-1 well and the HNWR-1A exploratory data, which suggests that the water type entering the well screens does not vary significantly when each well is pumped across the range of flows utilized during step-rate testing. The average specific conductance measurement collected during the step-rate test for HNWR-1A was 999 microSiemens per centimeter (μS/cm), which is consistent with the measurements collected from the corresponding depths in the respective exploratory borehole. Oxidation-reduction potential and dissolved oxygen measurements also remained consistent during the respective tests, and are representative of the aerobic water observed at these depths in the exploratory boreholes. Measurement of pH was consistent with HNWR-1 well and the exploratory borehole at approximately 8.2.

Temperature measurements were consistent throughout the step-rate test and consistent with measurements collected during the exploratory sampling. The average temperature during the step-rate test was approximately 36.2 degrees Celsius (approximately 97.2 degrees Fahrenheit) at HNWR-1A. Comparing this temperature data to that from the groundwater on the California side of the Colorado River, the average temperature in the monitoring wells within the planned injection zone for the groundwater remedy is 29.6 degrees C, calculated among the means at each well. The overall range in temperature measurements is 23.2 to 34.7 degrees C. The density at 36.2 degrees, which was the average measurement at HNWR-1A, is approximately 0.003 kilograms per liter (kg/L) lower than that at 29.6 degrees, assuming equal TDS. This slight difference is not expected to cause a significant separation between injected and receiving waters, especially given the inherent heterogeneity of the alluvial aquifer. Also, the 7-degree difference in temperature is not significant enough for the warmer water to cause greater leaching of matrix minerals, since the solubility of the various oxides, hydroxides, and silicate minerals are virtually identical at these two temperatures.

Metals. The concentrations of metals detected in samples collected during the step-rate test were consistent throughout each respective step. Detected concentrations of dissolved arsenic ranged from 12 to 14 μg/L, total chromium ranged from 15 to 16 μg/L and dissolved hexavalent chromium ranged from 17 to 18 μg/L. Arsenic and chromium (total and hexavalent) concentrations are lower than those detected previously in the HNWR-1 and Site B Wells.

Organics. Organic analyses included perchlorate, TPH, pesticides, PAHs, PCBs, and herbicides. All results for the organic analysis were non-detect.

Other Constituents. Other analyses including bromide, chloride, fluoride, nitrate/nitrite as nitrogen, soluble silica, sulfate, and total organic carbon were all consistent with the concentrations detected in samples from the exploratory borehole and HNWR-1 well. Results for gross alpha and gross beta were below the respective California maximum contaminant levels for drinking water, which are 15 and 50 picocuries per liter, respectively.

The results for stable isotopes of hydrogen and oxygen from samples collected during the step-rate test are consistent with the results of other samples collected during the evaluation from the HNWR-1 Site and Site B (see Table 8).

3.2 Site B Well Flow Profile Testing

The groundwater samples associated with the Site B well flow profile test were collected on June 12, 2014 at the Site B well.

Dynamic Flow Profile Testing. Based on the 13 discrete depth dye injection points from 140 to 310 ft bgs, the flow contribution along the length of the well (flow profile) was evaluated (see Attachment B, Table B-1). The Site B well was constructed with 3-screened zones and the percent flow contribution for each screened zone is as follows:

- Upper Screen, 145-185 ft bgs: 27%
- Middle Screen, 195-245 ft bgs: 58%
- Lower Screen, 265-305 ft bgs: 15%

The individual portions of the well that contributed the greatest flow were 25 percent from 175-185 ft bgs and 45 percent from 205-225 ft bgs.

Analysis of Water Quality Data. This section presents the results of field water quality measurements (Table 1) and laboratory analysis of the nine groundwater samples collected during the Site B well flow profile testing event (Tables 2 and 8). The nine samples collected during flow profile testing within the Site B well at various depths are representative of a cumulative or combined condition across the entire screened interval below the specific listed sample depth (the samples are collected while pumping with the pump intake positioned above the screen); therefore, the sample collected at the Site B wellhead (0 ft sample) is representative of a combined condition across the entire screened interval of the well. These results are then evaluated with the results of the profile of flow contribution to calculate a flow-weighted concentration. The next three subsections discuss the results of these samples empirically, and the last subsection presents the calculated flow-weighted concentration profile.

Field Measurements. Field water quality measurements, including specific conductance, temperature, pH, oxidation-reduction potential and turbidity, were monitored during flow profile sampling activities. The water quality measurements collected during the Site B flow profile test were consistent with the Site B constant-rate, step-rate test results and the Site B exploratory data, which suggests that the water type entering the well screens does not vary significantly with depth. The average specific conductance measurement collected during the Site B flow profile test was 1,320 microSiemens per centimeter (μS/cm). Temperature measurements were also consistent for the various depths during flow profile testing and compared to temperature measured during constant-rate and step-rate testing at the Site B well (conducted during February 2014, Phase 1). The average temperature during Site B flow profile testing was approximately 35.2 degrees Celsius (approximately 95.4 degrees Fahrenheit). Measurement of pH was consistent with previous Site B tests and the average pH of all sample depths was approximately 8.07. Oxidation-reduction potential measurements also remained consistent during the flow profile sampling and were representative of the oxidizing water observed at these depths in the exploratory boreholes and

measured during constant-rate and step-rate testing. Turbidity remained below 2.0 for all samples collected during flow profile testing.

Metals. The reported concentration of metals detected in the 0-ft sample collected during flow profile testing was consistent with sampling conducted during the Site B well constant-rate test. Detected concentrations of dissolved arsenic for the 0-ft sample was 17 μg/L and for the 8 depth specific samples results ranged from 16 to 18 μg/L. Detected concentrations of dissolved hexavalent chromium for the 0-ft sample was 34 μg/L and for the 8 depth specific samples results ranged from 36 to 38 μg/L. Hexavalent chromium concentrations were slightly higher than those detected previously during the Site B well constant-rate test.

Other Constituents. Other analyses including fluoride and TDS were consistent with the results from samples collected during the Site B well constant-rate test. The concentration of fluoride detected in the 0-ft flow profile sample was 4.2 μg/L. The concentration of fluoride detected in the 140 ft to 255 ft samples ranged from 4.0 to 4.3 μg/L. TDS concentrations ranged from 610 to 800 mg/L for samples collected during flow profile testing with the greatest concentration measured in the deepest sample.

Calculated Flow-weighted Concentration Profile. The laboratory analytical results for the zone-specific and the 0-ft (pump effluent) samples were evaluated with the results of the profile of flow contribution to calculate a flow-weighted concentration profile using the principles of conservation of mass. Based on this calculated profile, zones of relatively higher flow in the Site B well (approximately 175 to 285 feet bgs) have little water quality stratification. The flow contribution of the shallowest screened interval (approximately 145 to 175 feet bgs) was too low to allow for accurate calculation of a flow-weighted concentration.

4.0 Recommendations for Design of the Groundwater Remedy

The following conclusions about the freshwater supply for the groundwater remedy are based on review of hydraulic and water quality data collected during both phases of this evaluation:

- **HNWR-1 water quality and well performance.** Based on data collected during Phase 1, HNWR-1 will currently supply enough water of sufficient quality to supply the groundwater remedy at the nominal design flow rate of 450 gallons per minute (gpm), but not the maximum flow rate of 900 gpm. While the construction of the well was sufficient for its original intent (irrigation), it is not sufficient for long-term daily operation as a reliable element of the groundwater remedy. Due to the design and construction of the well the options for aggressive and effective well maintenance are limited. Further, operational flexibility to lower the pump and generate more flow is limited by the smaller diameter of the lower portion of the well.
- **Site B water quality and well performance.** Based on data collected during Phase 1, the Site B well will supply enough water to support the maximum designed remedy flow rate and the well construction allows optimal flexibility for operation (i.e., pump depth) and maintenance options; however, based on current well construction and operation during testing, the water quality is currently not optimal. The Site B well flow profile testing and associated zone-specific groundwater sampling conducted during Phase 2 suggests that the well currently has little water quality stratification; therefore, it is unlikely that modification to the well construction will result in a change in the water quality produced from the well.
- **HNWR-1A water quality and well performance.** Like nearby well HNWR-1, water quality from the HNWR-1A well is adequate to supply the groundwater remedy; however, unlike HNWR-1, the quantity of water that the well will produce exceeds the maximum estimated demand for remedy operation. Further, the well construction is sufficient for long-term daily operation as a reliable element of the groundwater remedy and is suitable for a range of well maintenance options, as determined necessary during remedy operation.

- **EIR Mitigation Measures WATER-1.** 72-hour constant-rate extraction tests conducted during Phase 1 at both HNWR-1 and the Site B well suggest that neither will substantially adversely affect the production rates of existing nearby wells (see EIR Mitigation Measure WATER-1, Addendum No. 1). Data collected during these tests were used to update the groundwater flow model for the Arizona side of the Colorado River. The updated model was re-run to simulate drawdown in nearby well Topock-2 with the operation of HNWR-1A, which has a slightly different construction than HNWR-1, at the nominal flow design flow rate of 450 gpm. This simulated pumping in HNWR-1A results in an additional 0.1 feet of drawdown compared to HNWR-1; therefore, pumping at HNWR-1A also will not substantially adversely affect the production rates of existing nearby wells.

Based on this information the recommended path forward for establishing a freshwater supply for the groundwater remedy that provides the maximum flexibility and reliability includes:

1. Utilization of HNWR-1A as the primary freshwater supply for the groundwater remedy.
2. Designing the infrastructure required to plumb and operate the HNWR-1 well as a secondary freshwater supply.
3. Designing the infrastructure required to plumb and operate the Site B well as a contingency freshwater supply. While the Site B well will provide an adequate quantity of water, blending with another supply will likely be required to lower the naturally occurring hexavalent chromium concentration below 32 μg/L.

LEGEND

NOTE:
The lithology shown here was obtained from available driller's well logs and has not been independently verified by CH2M HILL with the exception of Site B and HNWR-1A exploratory borings to 400ft.

* In an effort to improve water quality the two deep screens in Topock-3 were isolated after installation. This well currently produces water from the shallow-most screen only.

Notice of Intent to Drill, Deepen, Replace or Modify a Well

(except a Non-Exempt Well in an Active Management Area)

$150 or $100 FEE

- Review instructions prior to completing form in black or blue ink.
- You must include with your Notice:
  - Check or money order in the amount of the appropriate filing fee.
  - For a well located within an AMA or INA, the fee is $150.00.
  - For a well not located within an AMA or INA, the fee is $100.00 if the well will be used solely for domestic purposes (see page 2 and instructions) and will have a pump with a maximum capacity of not more than 35 gallons per minute. Otherwise, the fee is $150.00.
- Authority for fee: A.R.S. § 45-596 and A.A.C. R12-15-104.

SECTION 1. COUNTY OR LOCAL HEALTH AUTHORITY APPROVAL (if applicable)

If water from the proposed well will be used for domestic purposes on a parcel of land of 5 or fewer acres, the applicable county or local health authority must endorse all items in Section 1 within one year before submission to the Department of Water Resources. You must also attach a site plan (pg. 3).

CHECK ONE

☐ County or Local Health Authority Recommends Approval (pursuant to A.R.S. § 45-596 (G) and (F))
- ☐ Field Inspection Performed
- ☐ Site Plan Review Only

☐ Insufficient Information to Make a Determination

Official County or Local Seal or Stamp

COUNTY OR LOCAL AUTHORITY NAME AND TITLE

TELEPHONE NUMBER | DATE | COUNTY OR LOCAL AUTHORITY SIGNATURE

SECTION 2. REGISTRY INFORMATION

Well Type

CHECK ONE

☐ Exempt
(Pump has a maximum capacity of not more than 35 gpm and water is not used for irrigation purposes inside an AMA.)
(See instructions.)

☒ Non-Exempt
(Pump has a maximum capacity of more than 35 gpm and the well is located outside an AMA.)
(See instructions.)

DESIGN PUMP CAPACITY: 1,000 Gallons Per Minute

Proposed Action

CHECK ONE

☒ Drill New Well
☐ Deepen
☐ Replace
☐ Modify

If Deepening, Replacing or Modifying:

ORIGINAL WELL REGISTRATION NUMBER: 55 - NA

MAXIMUM CAPACITY OF ORIGINAL WELL: NA Gallons Per Minute

DISTANCE & DIRECTION FROM ORIGINAL WELL: NA Feet

SECTION 4.

Questions	Yes	No	If Yes:
1. Is the proposed well site within 100 feet of a septic tank system, sewer disposal area, landfill, hazardous materials or petroleum storage area or tank?		☒	You must also request a variance (A.A.C. R12-15-818).
2. Is there another well name or identification number associated with this well (e.g., Lot 35 Well, Smith Well, etc.)?		☒	PLEASE STATE
3. Is the proposed well a NEW well to be located within an Active Management Area? *(See instructions.)*		☒	Unless the well is a replacement well and the total number of operable exempt wells on the land is not increasing, you must also file a supplemental form A.R.S. § 45-464(C) & (D).
4. Is the proposed well the second exempt well on this parcel for the same use?		☒	If the proposed well is in an Active Management Area, you must also file a supplemental form A.R.S. § 45-454(I).

☐ Other* (please specify):	☐ Other* (please specify):

NOTE: If this is a Notice of Intent to construct a new well that will be used for the purpose of withdrawing groundwater for transportation to an Active Management Area (AMA) pursuant to A.R.S. § 45-552, 45-553, 45-554 or 45-555(A), the authorization to drill the well issued in association with this Notice shall not be considered the approval to transport groundwater to an AMA. *(see instructions.)*

SECTION 7. PROPOSED WELL CONSTRUCTION DESIGN (attach separate sheet if needed)

Borehole			Casing													
DEPTH FROM SURFACE			DEPTH FROM SURFACE			MATERIAL TYPE (T)				PERFORATION TYPE (T)						
FROM (feet)	TO (feet)	BOREHOLE DIAMETER (inches)	FROM (feet)	TO (feet)	OUTER DIAMETER (inches)	STEEL	PVC	ABS	IF OTHER TYPE, DESCRIBE	BLANK OR NONE	WIRE WRAP	SHUTTER SCREEN	MILLS KNIFE	SLOTTED	IF OTHER TYPE, DESCRIBE	GROUTING MATERIAL
0	480	26	0	100	14.625	X*				X						Cement
			100	400	14.625	X					X					

* ADWR well construction standards require a surface seal consisting of a minimum of 20 feet of steel casing. Cement grout must be used to fill the annular space between the surface casing and the borehole. (A.A.C. R12-15-811(B))

The Department's issuance of an authorization to drill a well is not a determination of whether water withdrawn from the well is legally surface water or groundwater. The legal nature of the water withdrawn from the well may be the subject of court action in the future as part of a determination of surface water rights in your area. If there are court proceedings that could affect your well, you will be notified and be given the opportunity to participate. If you have questions regarding the legal nature of the water to be withdrawn from your proposed well, please consult with an experienced civil engineer, hydrologist or water rights attorney.

For the purpose of determining appropriate fees outside AMAs or INAs, "domestic purposes" is defined as "uses related to the supply, service and activities of households and private residences and includes the application of water to less than 2 acres of land to produce plants or parts of plants for sale or human consumption, or for use as feed for livestock, range livestock or poultry, as such terms are defined in A.R.S. § 3-1201."

SECTION 8. OPTIONAL BY PROPERTY OWNER AND WELL OWNER ONLY

☐ By checking this box, I hereby provide ADWR permission to enter the property for the purpose of taking water level measurements at this well. *(See instructions.)*

SECTION 9. WELL OWNER AND PROPERTY OWNER SIGNATURE

I state that this notice is filed in compliance with A.R.S. § 45-596 and is complete and correct to the best of my knowledge and belief.

TYPE OR PRINT NAME AND TITLE: Curt Russell (PG&E Topock Project Site Manager), Linda Miller (Refuge Manager)

Video Survey Report

Company:	Groundwater Partners Inc.	**Date:**	09-Jul-14		
Well:	HNWR-1A	**Run No.**	One	**Truck**	PS-5
Field:	Topock	**Job Ticket:**	18287		
State:	Arizona	**Total Depth:**	204 ft		
		Water Level:	6 ft	SWL	
Location:	1.5 miles north of Golden Shores	**Oil on Water:**	No	**Amount:**	0 ft
	GPS: N34o43.405' W114o28.699'	**Operator:**	Abreau		
Zero Datum:	Ground Level **Tool Zero:**	Side-Scan		**Dead Space**	1.75 ft
Reason for Survey:	New Well Construction	**Guides Set @**	13.0 in		

Depth	Observations		
0.0 ft	Begin survey from ground level.	**Perforation:**	**From Survey**
6.1 ft	SWL; Water clear, visibility good.	Wire-Wrap	63.20 ft to 132.60ft
20.0 ft	Casing appears normal and in good condition.		154.30 ft to 193.70ft
63.2 ft	Top of perforations, perforations appear open and in good condition.		
66.0 ft	Perforations appear open, with visible gravel pack.		
85.0 ft	Perforations appear open, with visible gravel pack.		
132.6 ft	Bottom of perforations, perforations appear open within interval.		
140.0 ft	Casing appears normal and in good condition.		
154.3 ft	Top of perforations, perforations appear open and in good condition.		
162.0 ft	Perforations appear open, with visible gravel pack.		
191.0 ft	Perforations appear open, with visible gravel pack.		
193.7 ft	Bottom of perforations, perforations appear open with few localized small bio-growth patches.	**Casing Size**	**From Survey**
203.8 ft	Fill; End Survey.	14.0 in	0.00 ft to 203.80ft

Notes:

1 All sampling was conducted at Site B Well on June 12, 2014.

2 The purge rate during sampling (and 24 hours prior to sampling) was 986 gpm.

3 Reported analytical results are dissolved

4 All data analysis including calculation of flow contribution and flow weighted concentrations performed by BESST, Inc.

5 The flow contribution of this zone is too small to allow for accurate calculation of a flow-weighted concentration.

6 Flow data from the intervals 215'-225' and 225'-235' flow results were inconclusive due to equipment mechanical issues at the time of injection. Therefore the flow data from 215' to 235' was calculated at 239 gpm over a 20' interval instead of two 10' intervals. The same is true for the interval 145'-165', which had a total flow contribution of 5 gpm.

ug/L - Micrograms per liter

mg/L - Milligrams per liter

feet - feet below ground surface

gpm - gallons per minute

TDS - total dissolved solids

U.S. Geological Survey Combined Well-Bore Flow and Depth-Dependent Water Sampler

The U.S. Geological Survey has developed a combined well-bore flow and depth-dependent sample collection tool. It is suitable for use in existing production wells having limited access and clearances as small as 1 inch. The combination of well-bore flow and depth-dependent water-quality data is especially effective in assessing changes in aquifer properties and water quality with depth. These are direct measures of changes in well yield and ground-water quality with depth under actual operating conditions. Combinations of other geophysical tools capable of making these measurements, such as vertical-axis current meters used with wire-line samplers, are commercially available but these tools are large and can not easily enter existing production wells.

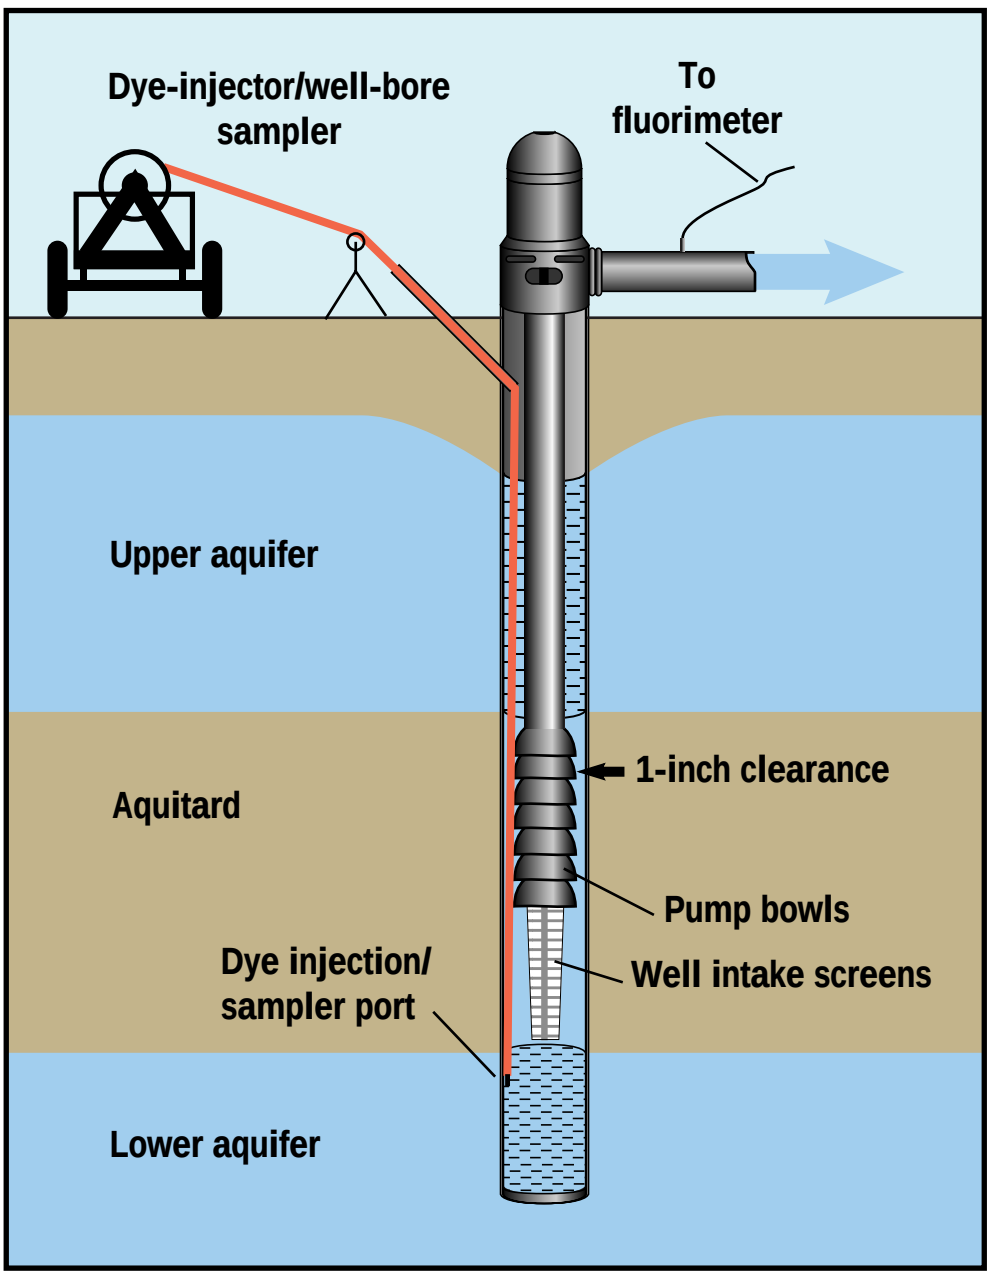

Figure 1. Example of typical deployment in a deep-turbine production well.

BASIC OPERATING PRINCIPLES

The U.S. Geological Survey device is a high-pressure hose equipped with valves for dye injection and sample collection. The hose is mounted on a reel for deployment, retrieval, and storage (fig. 1). The hose can be used to collect velocity-log data and, after cleaning and decontamination, the same hose can be used to collect depth-dependent water-quality data. Accessories, such as a Teflon® hose extension, are available for collection of organic compounds.

Velocity-Log Data

The equipment is used to obtain flow data within the well bore under pumping conditions using a technique we named the 'tracer-pulse method.' When operated in this mode, the hose is filled with fluid containing an easily measured tracer, such as water colored with Rhodamine dye. The hose is lowered to a known depth in the well (d_1) and a pulse of the tracer is injected into the water column. The travel-time of the tracer to a detector on the surface is measured (t_1). If Rhodamine dye is used, a commercially available fluorimeter is used to measure the arrival of the dye at the surface. The hose is then lowered to the next depth (d_2), another pulse of dye is released, and the travel-time is measured (t_2). The velocity is calculated as the difference in the travel-times. Assuming piston flow, the flow rate (Q), given a known well radius (r), is calculated using the following equation:

$$Q = (V\pi r^2) \quad \text{where: } V = (d_2-d_1)/(t_2-t_1)$$

A series of injections at different depths is done to construct a velocity profile for the well. The velocity profile can then be used to guide the collection and interpretation of depth-dependent water-quality data.

Depth-Dependent Water-Quality Data

To collect a water-quality sample from a given depth in the well, the hose is pressurized to greater than the hydrostatic pressure at that depth and lowered into the well. When the sample depth is reached, the hose is vented at the surface and water from the well at the sample depth enters the hose. The hose is retrieved and the sample expelled from the hose under pressure. The process is repeated at several depths to complete a water-quality profile within the well. If the concentrations of a constituent at the first sample depth (C_1) and the second sample depth (C_2) are known, the concentration in water entering the well from the intervening water-bearing zone (C_a) can be calculated from the water-quality profile and the velocity-log data:

$$[(C_1Q_1-C_2Q_2)/Q_a] = C_a$$
$$\text{where } Q_a = (Q_1 - Q_2)$$

This calculation assumes conservative mixing and conservation of mass.

APPLICATIONS

The data shown in figure 2 are from a deep production well in a complex multiple-aquifer system. These data illustrate changes with time in the chloride concentration of water entering the well at depth and changes with time in the distribution of flow into the well. Because changes in well yield and water quality measured at the surface were small, these changes would not have been detected using conventional sample collection methods which are a composite of all the water flowing into the well. A comparison of data from a velocity log using a conventional spinner tool and a velocity log using the tracer-pulse method also is shown in figure 2. The tracer-pulse method correctly identified the most important water-yielding zone and the depth below which almost no water enters the well. Neither of these important hydrologic features could have been identified on the basis of indirect data, such as a resistivity log (fig. 2).

The combination of velocity-log data and depth-dependent water-quality data is an especially effective data set for hydrologic interpretations. Specific applications for data collected using this approach include:

(1) Identification of changes in ground-water quality and well yield with time.
(2) Identification of different water-bearing units with depth.

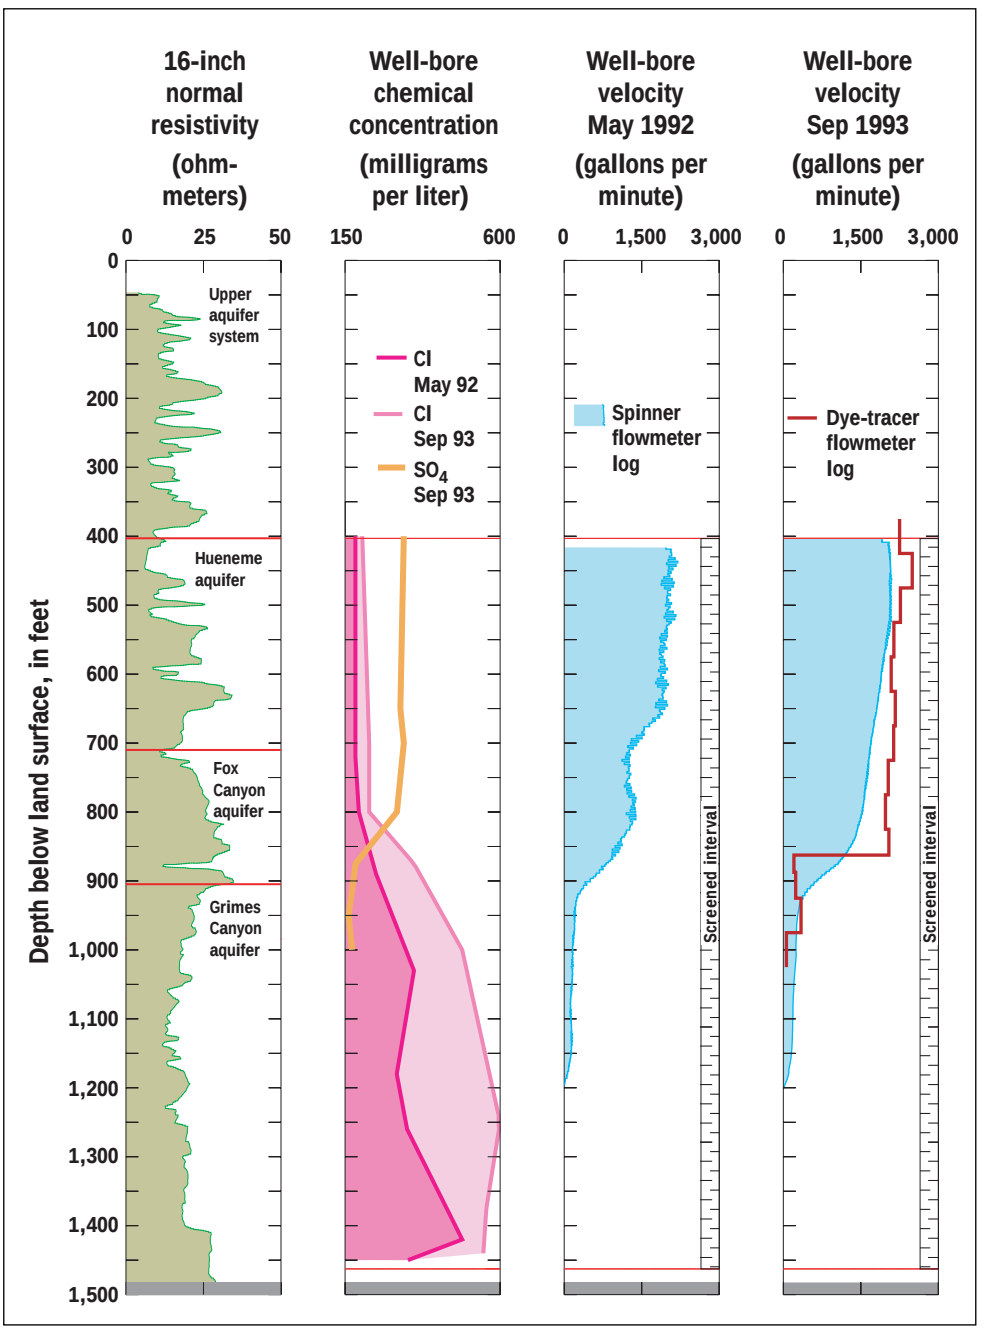

Figure 2. Example of depth-dependent flow and chemical data sampled from a deep production well.

(3) Identification of changes in natural ground-water chemistry with depth.
(4) Identification of man-made or natural contaminants with depth.

Although the applications described here are primarily for production wells, the approach also can be applied to observation wells. This approach may be especially useful to assess the performance of wells used for remediation if contaminants are stratified within the aquifer.

A SMALL-DIAMETER SAMPLE PUMP FOR COLLECTION OF DEPTH-DEPENDENT SAMPLES FROM PRODUCTION WELLS UNDER PUMPING CONDITIONS

By John A. Izbicki

The U.S. Geological Survey, in cooperation with the manufacturer ([1]Besst In$_2$c. http://www.besstinc.com), has modified a commercially available gas-displacement sample pump to collect water at selected depths within production wells under pumping conditions. The modified pump is about 6 inches long, less than 1 inch in diameter, and is operated through repeated application and release of compressed gas. The pump is intended for use in production wells having limited access that prevents the use of traditional geophysical tools, such as wire-line bailers, used to collect depth-dependent water samples. In most cases, the production pump does not have to be removed or the well modified for insertion of the sample pump. Data collected at different depths within the production well reflect water quality at those depths under actual pumping conditions. If well-bore flow velocities are known, the quality of water in the aquifer between sample depths can be estimated.

DESIGN AND BASIC OPERATING PRINCIPLES OF THE SAMPLE PUMP

The modified sample pump consists of a series of one-way flow valves connected to the surface by two 1/8-inch-diameter Teflon tubes bonded together into a single hose. One tube serves as a pressure line, and the other serves as the sample line (fig. 1). After the pump is lowered into the well to the sample depth, water enters the pump, filling both Teflon tubes to the water level in the well (Initial conditions, fig. 1). The pressure line is pressurized using compressed gas, and water is displaced from this tube into the sample line (Pressure cycle, fig. 1). A one-way flow valve at the pump intake prevents the displaced water from flowing back into the well. Once the water is in the sample line, another one-way valve prevents the water from flowing back toward the sample pump after pressure is released (Release cycle, fig. 1).

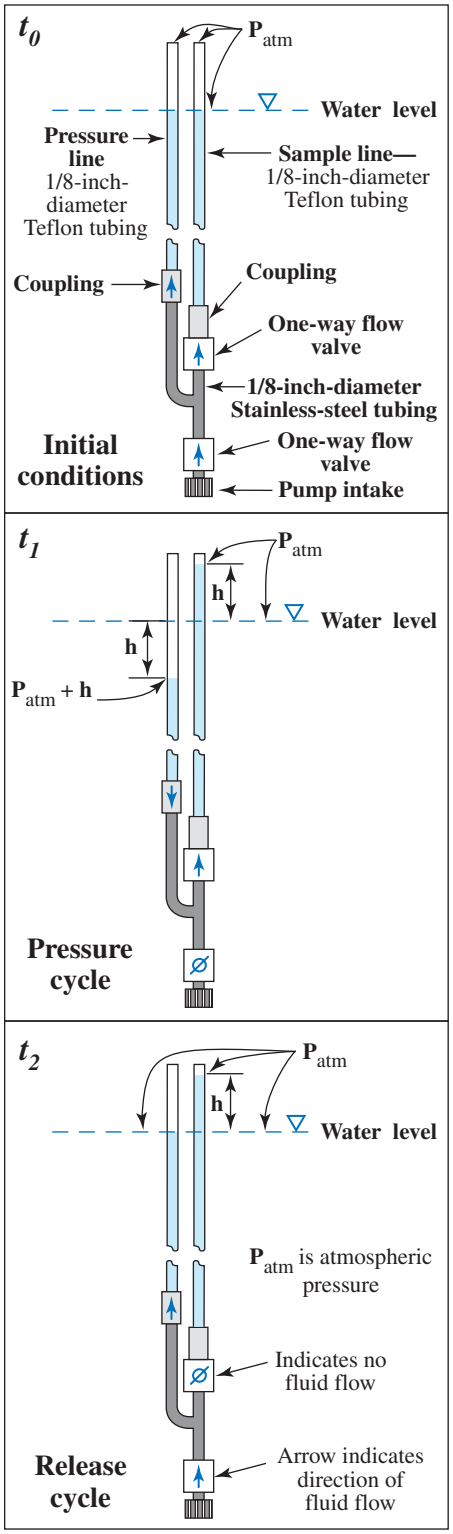

Figure 1. Diagram showing schematic of small-diameter pump and basic operating principles.

To force additional water into the sample line, pressure is alternately applied and released on the pressure line at the surface using compressed gas regulated through a control panel built by the U.S. Geological Survey. The column of water in the sample line can be forced upward to the surface through the sequential application and release of pressure. Alternately, when sufficient volume is accumulated, water in the sample line can be forced to the surface using compressed gas. With proper use, water from the pump is suitable for analysis for a wide variety of constituents, including volatile organic carbon and dissolved gasses. The pump is capable of lifting water from depths as great as 1,200 feet. The pump and hose are mounted on a motorized reel (fig. 2).

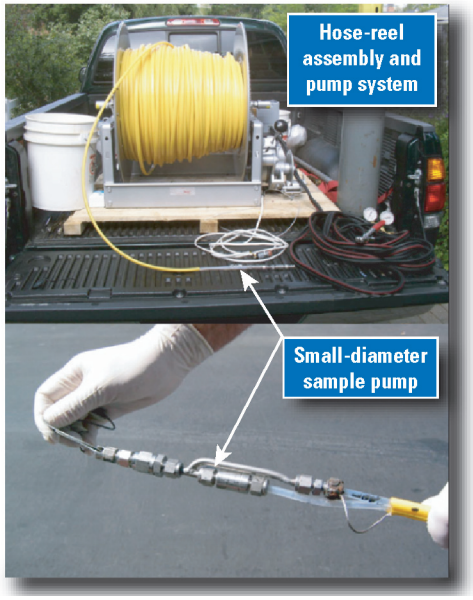

Figure 2. Photograph showing a) hose-reel assembly and b) small-diameter sample pump.

Samples from different depths within production wells can be collected by sequentially moving the pump to a different sample-collection depth without retrieving the pump from the well after each sample is collected. The pump pro-

vides an alternative to traditional sample-collection methods using wire-line bailers or sample-collection methods developed by Izbicki and others (1999), both of which require sample equipment to be pulled from the well to bring each depth-dependent sample to land surface.

DATA INTERPRETATION

Depth-dependent water-quality data collected within production wells under pumping conditions can be used to estimate the quality of water yielded to a well from a selected depth interval using the following equation:

$$C_a = (C_i Q_i - C_{i+1} Q_{i+1})/Q_a , \quad \text{(eq. 1)}$$

where:

C is the concentration of a given constituent,

Q is the flow of water within the well (either as volume per unit time, as velocity, or as percent of total discharge),

i is the first sample collection and flow measurement depth,

$i+1$ is the second sample collection and flow measurement depth, and

a is the interval between i and $i+1$.

(In this example, flow in the well is presumed to be upward toward the pump intake and the first sample-collection depth is shallower than the second sample-collection depth.)

Depth-dependent water-quality data collected from production well 4N/5W-2H1 near Victorville, California, using this small-diameter sample pump are shown in figure 3. The well is screened between 600 and 836 feet below land surface, and the pump intake is at 685 feet. The well was pumped at 1,000 gallons per minute. Flow was upward from the bottom of the well screen toward the pump intake. The deepest sample collected from the well is presumed to be representative of water in the aquifer at that depth. The next deepest sample is a mixture of water already in the well and water that entered the well between the two sample depths. The combination of velocity-log and depth-dependent water-quality data can be used to resolve the mixture within the well and estimate the concentration of a constituent in water contributed from the aquifer to the well at selected sample depths below the pump intake during pumping (fig. 3). Results of calculations show that, in general, arsenic concentrations increased with depth below the pump intake but remained below the U.S. Environmental Protection Agency proposed Maximum Contaminant Level for arsenic of 10 micrograms per liter (µg/L).

Flow was downward in the well from the top of the screened interval to the pump intake (fig. 3). No samples were collected above the pump intake and the arsenic concentration of water yielded from the aquifer to the well above the pump intake was not calculated.

DISCUSSION

The small-diameter pump provides a means to collect depth-dependent water-quality data from specific intervals in long-screened production wells under pumped conditions. Coupled depth-dependent water-quality and velocity-log data have application to a wide range of hydrologic problems including seawater intrusion, brine invasion, naturally occurring trace-elements, and anthropogenic contamination. The small-diameter sample pump described in this fact sheet enables more efficient collection of depth-dependent samples from production wells having limited access by increasing the ease with which water samples are collected (thereby reducing the time and cost) through eliminating the need to retrieve the sample pump from the well after each sample is collected.
